

Materials 38 - Bias in the neighborhood of zero forecast errors

Laura Gáti

July 24, 2020

Overview

1	Simulated “true” data	2
2	Real data with the SPF	12
A	Model summary	15
B	Target criterion	15
C	Impulse responses to iid monopol shocks across a wide range of learning models	16

1 Simulated “true” data

3 potential causes to lack of identification in the zero neighborhood

1. The distribution of estimates is skewed \rightarrow take $median(\hat{\alpha})$ instead of the mean.
2. The truth is based on a simulation that doesn't favor the zero neighborhood \rightarrow do 100 simulations from the “true” parameters and take the mean moments of those.
3. The gain doesn't matter if the forecast error is 0, or very close to it \rightarrow introduce a distinction between the forecast error that's used to choose the gain and the one used to update the coefficients of the learning rule.

+1 Taking mean moments across N histories is more natural than performing the estimation N times.

+2 Introduce expectation series (SPF)

Reference for comparison: Fig 1. of Materials 37

Figure 1: Reference figure: Mean estimates for $N = 100$, imposing convexity with weight 100K, truth with $nfe = 5, fe \in (-2, 2)$

Point #1: skewness \rightarrow take median instead of mean

Figure 2: Mean estimates for $N = 100$, imposing convexity with weight 10K, truth with $nfe = 5, fe \in (-2, 2)$

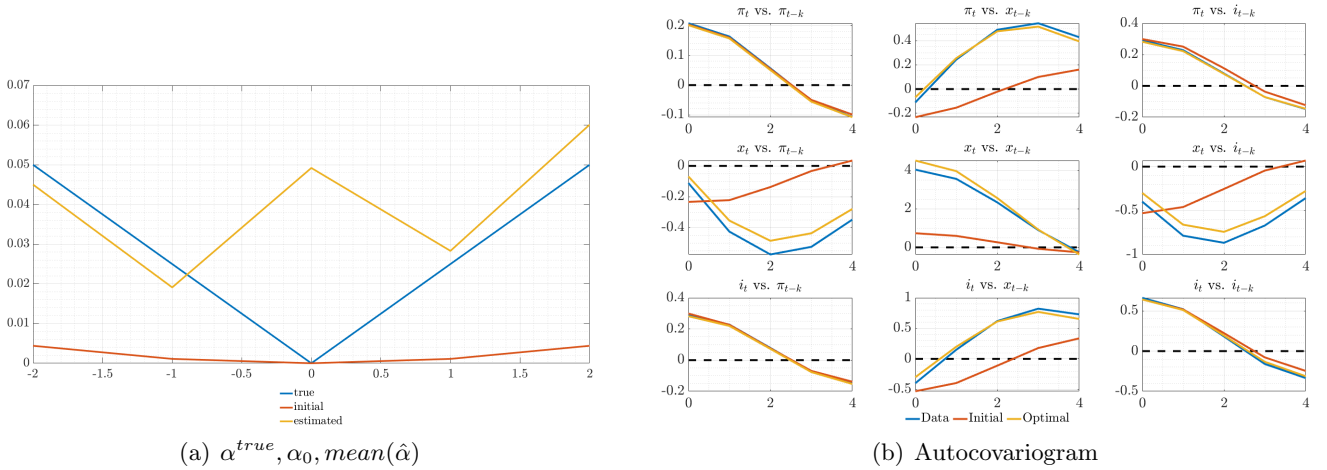

(a) $\alpha^{true}, \alpha_0, mean(\hat{\alpha}), median(\hat{\alpha}),$ unsorted median

I understand what's happening! Half the estimates are L's, the other half are “inverted L's”, which is why taking a mean or a classical, sorted median has the tendency to produce these nonmonotonic zigzags.

Point #2: do 100 truths

Figure 3: Estimates for $N = 100$, **truth is a mean of 100 simulations**, imposing convexity with weight 100K, truth with $nfe = 5, fe \in (-2, 2)$

That didn't help, did it now?

Point #3: change timing of forecast errors

$$k_t^{-1} = \mathbf{g}(fe_{t|t-1}) \quad (1)$$

$$\bar{\pi}_t = \bar{\pi}_{t-1} + k_t^{-1} fe_{t|t-1} \quad (2)$$

The issue seems to be: if $fe_{t|t-1} \approx 0$, then the gain is irrelevant for learning because $fe_{t|t-1}$ figures into both equations. So the idea is to decouple the two equations by changing the timing of one of the forecast errors. Note:

$$fe_{t|t-1} = \pi_t - (\bar{\pi}_{t-1} + bs_{t-1}) \quad (3)$$

$$= \pi_t - \bar{\pi}_{t-1} \quad \text{since shocks iid and } b \text{ is the RE transition matrix} \quad (4)$$

So what I can try is to use an older forecast error in equation (2). Try $fe_{t|t-1} \equiv \pi_t - \bar{\pi}_{t-2}$.

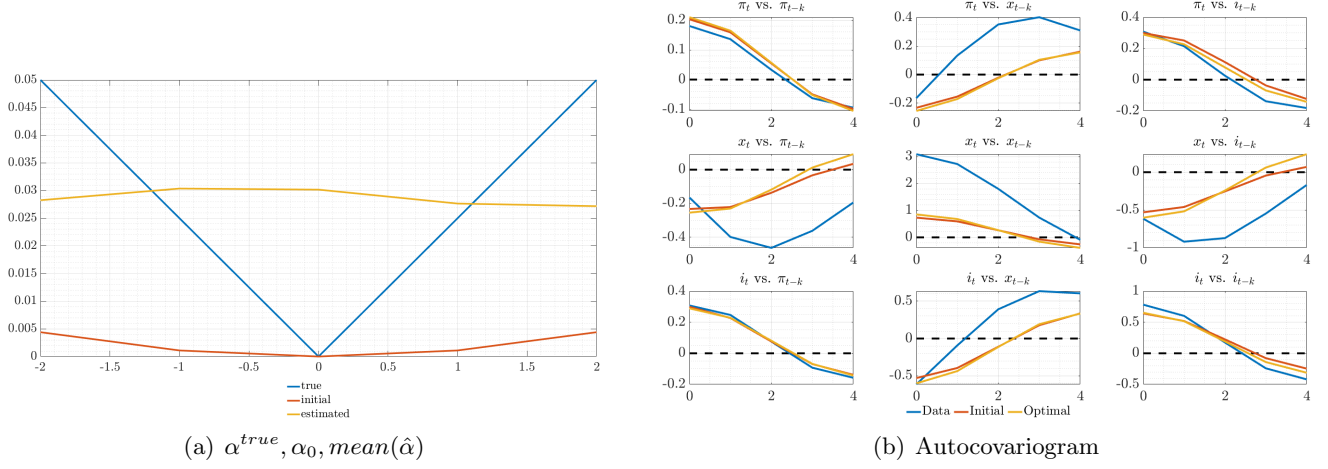

Figure 4: Estimates for $N = 100$, **changing the forecast error timing in the updating equation**, imposing convexity with weight 100K, truth with $nfe = 5$, $fe \in (-2, 2)$

A little more symmetric, but no dramatic improvement.

Point #+1: do N simulations instead of N estimations

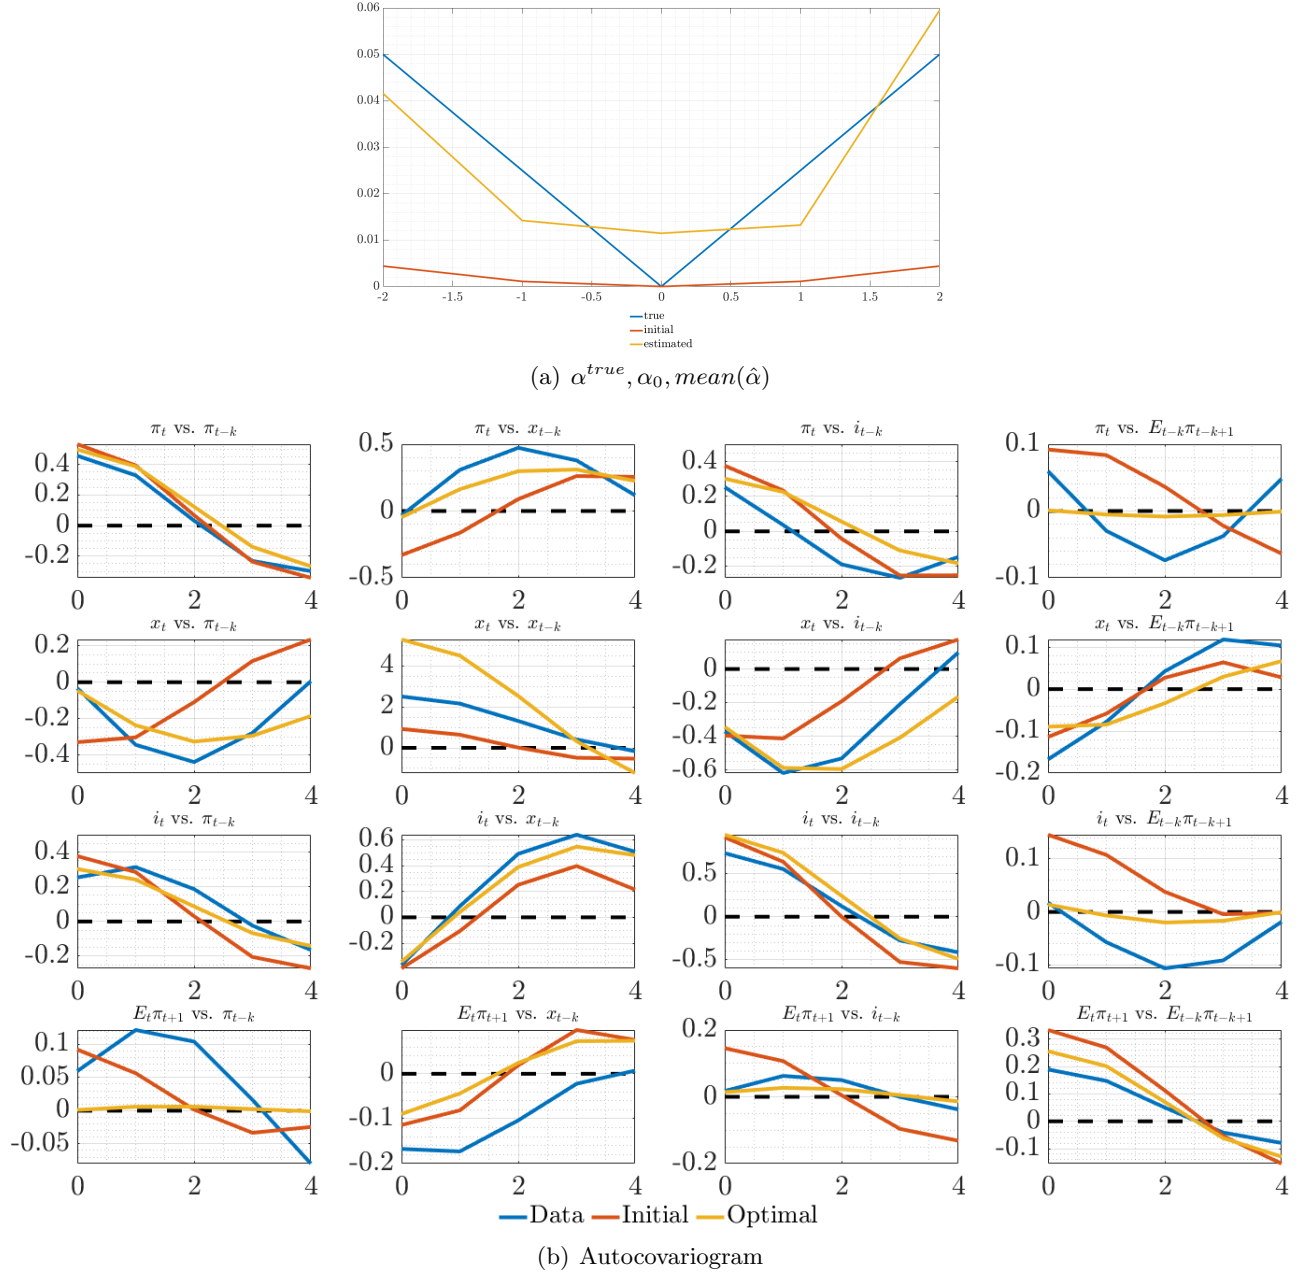

Figure 5: Estimates for $N = 100$, targeting mean moments in a single estimation instead of N estimations of individual moments, imposing convexity with weight 100K, truth with $nfe = 5$, $fe \in (-2, 2)$

The difference is striking!

Point #+2: introduce expectations series

Figure 6: Estimates for $N = 100$, incl. 1-step ahead forecasts of inflation, imposing convexity with weight 100K, truth with $nfe = 5, fe \in (-2, 2)$

I've added measurement error to π, x, i and the expectation to avoid stochastic singularity from having 4 observables and only 3 shocks.

This clearly has added useful info. Otherwise, behavior is like before:

- Without the convexity restriction, I still get nonconvex estimate.

- With the 0 at 0 restriction, I can match the 0 region, otherwise I can't.
- Both restrictions lead to basically identical moments.

Figure 7: Estimates for $N = 1000$, incl. 1-step ahead forecasts of inflation, imposing convexity with weight 100K, truth with $nfe = 5, fe \in (-2, 2)$

What's missing

To me it seems that the reason we're still underidentified is that the $(-1, 1)$ -forecast error region (possibly an even bigger, $(-1.5, 1.5)$ -region) doesn't produce variation in $\bar{\pi}$ (see Eq. 2). So let's try to replace the forecast error in the generation of the gain (Eq. 1) by say the forecast error of the output gap. (Needs the constant-only PLM.) → Doesn't work at all, I guess b/c it doesn't correspond to the DGP.

→ Really wonder if the anchoring function specified in terms of changes, not levels of the gain would help! If instead of equation 1 in system 1-2, we'd have

$$k_t^{-1} = \mathbf{g}(k_{t-1}^{-1}, fe_{t|t-1}) \quad (5)$$

No, even that wouldn't work b/c the estimation routine wouldn't be able to discriminate between two points on the line $(k_{(i)}^{-1}, fe \in (-1, 1))$, for $\forall i$ in the k -space.

→ I'm increasingly thinking that that region cannot be identified at all because it simply doesn't matter for the evolution of long-run expectations.

2 options:

1. Select gridpoints strictly outside the $(-1, 1)$ -region, and use the convexity restriction to interpolate inside the region.
2. Impose the 0 at 0 restriction at the point at 0, and select the rest of the gridpoints outside the $(-1, 1)$ -region.

If my conjecture is correct, both of these approaches should be identified.

Figure 8: Estimates for $N = 100$, incl. 1-step ahead forecasts of inflation, imposing convexity with weight 100K, truth with $nfe = 5$, $fe \in (-2, 2)$

Unfortunately, it seems to me like even outside the trouble region, we're not identified. I say that because the 0 at 0 assumption on its own should have no bearing on the coefficients out in the tails of the forecast error space. But also there, even with a high N , I'm not nailing the truth.

Figure 9: Estimates for $N = 1000$, incl. 1-step ahead forecasts of inflation, imposing convexity with weight 100K, truth with $nfe = 5$, $fe \in (-2, 2)$

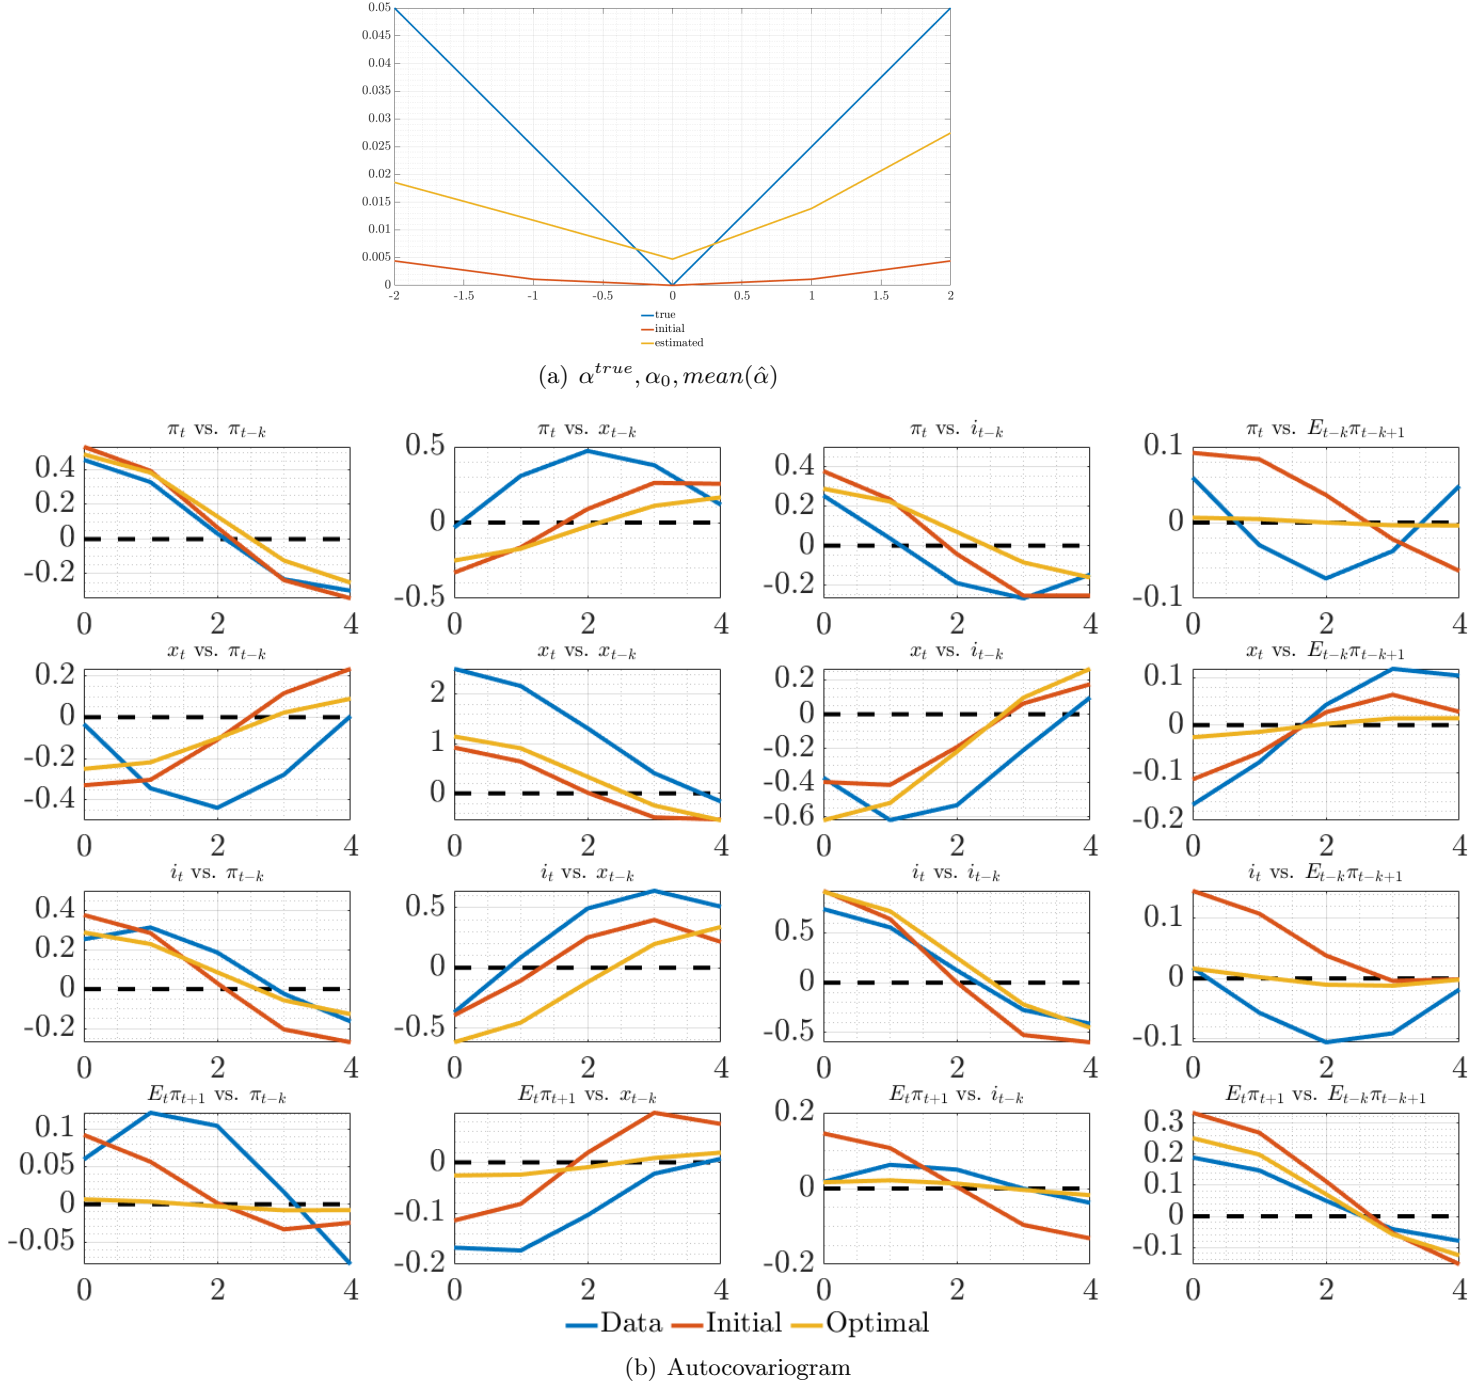

(a) $\alpha^{true}, \alpha_0, mean(\hat{\alpha})$, 4 knots: $(-2, -1, 1, 2)$

(b) $\alpha^{true}, \alpha_0, mean(\hat{\alpha})$, 5 knots: $(-2, -1, 0, 1, 2)$,
0 at 0 restriction imposed with weight 1K

(c) $\alpha^{true}, \alpha_0, mean(\hat{\alpha})$, 5 knots: $(-2, -1, 0, 1, 2)$,
0 at 0 restriction imposed with weight 1K,
convexity restriction removed

Figure 10: Estimates for $N = 100$, incl. 1-step ahead forecasts of inflation, imposing convexity with weight 100K, truth with $nfe = 5, fe \in (-2, 2)$, **single estimation of mean moments from N simulations**

This does make a difference and I think it improves on the moments vis-a-vis the N estimations case. However, it converges in the wrong direction with $N = 1000$. And it really depends on shocks! A seed of `rng(2)` instead of `rng(1)` makes a huge difference! This is not cleaning out the effect of shocks properly. The “ N -estimations” strategy however is robust to changing the seed.

2 Real data with the SPF

Figure 11: Estimates for $N = 1000$, incl. SPF 1-step ahead forecasts of inflation, imposing convexity with weight 100K, $nfe = 5$, $fe \in (-2, 2)$

Figure 12: Estimates for $N = 1000$, $nfe = 5$, $fe \in (-2, 2)$, incl. SPF 1-step ahead forecasts of inflation, removing convexity restriction, imposing 0 at 0 with weight 1K

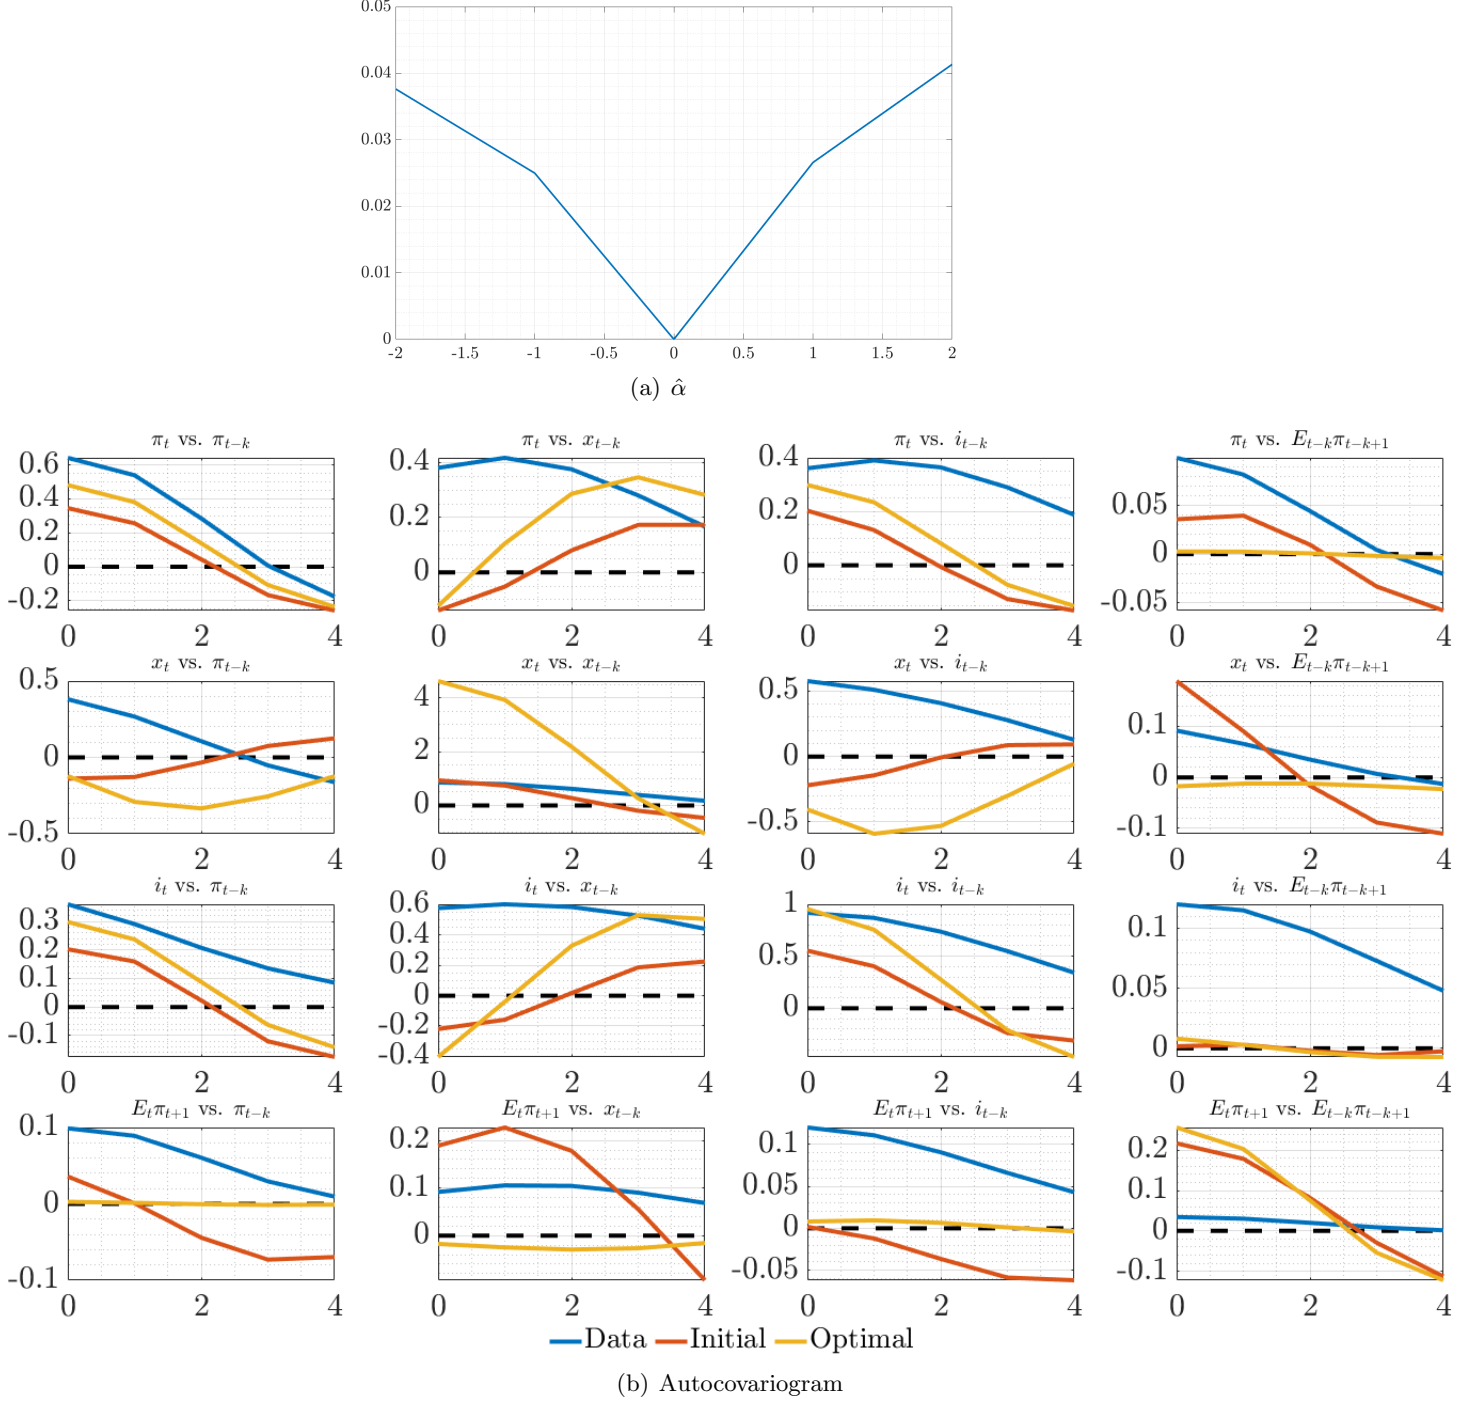

Figure 13: Estimates for $N = 1000$, incl. SPF 1-step ahead forecasts of inflation, imposing convexity with weight 100K, 5 knots, $fe \in (-2, 2)$

A Model summary

$$x_t = -\sigma i_t + \hat{\mathbb{E}}_t \sum_{T=t}^{\infty} \beta^{T-t} ((1-\beta)x_{T+1} - \sigma(\beta i_{T+1} - \pi_{T+1}) + \sigma r_T^n) \quad (\text{A.1})$$

$$\pi_t = \kappa x_t + \hat{\mathbb{E}}_t \sum_{T=t}^{\infty} (\alpha\beta)^{T-t} (\kappa\alpha\beta x_{T+1} + (1-\alpha)\beta\pi_{T+1} + u_T) \quad (\text{A.2})$$

$$i_t = \psi_\pi \pi_t + \psi_x x_t + \bar{i}_t \quad (\text{if imposed}) \quad (\text{A.3})$$

$$\text{PLM:} \quad \hat{\mathbb{E}}_t z_{t+h} = a_{t-1} + b h_x^{h-1} s_t \quad \forall h \geq 1 \quad b = g_x h_x \quad (\text{A.4})$$

$$\text{Updating:} \quad a_t = a_{t-1} + k_t^{-1} (z_t - (a_{t-1} + b s_{t-1})) \quad (\text{A.5})$$

$$\text{Anchoring function:} \quad k_t^{-1} = \rho_k k_{t-1}^{-1} + \gamma_k f e_{t-1}^2 \quad (\text{A.6})$$

$$\text{Forecast error:} \quad f e_{t-1} = z_t - (a_{t-1} + b s_{t-1}) \quad (\text{A.7})$$

$$\text{LH expectations:} \quad f_a(t) = \frac{1}{1-\alpha\beta} a_{t-1} + b(\mathbb{I}_{nx} - \alpha\beta h)^{-1} s_t \quad f_b(t) = \frac{1}{1-\beta} a_{t-1} + b(\mathbb{I}_{nx} - \beta h)^{-1} s_t \quad (\text{A.8})$$

This notation captures vector learning (z learned) for intercept only. For scalar learning, $a_t = (\bar{\pi}_t \ 0 \ 0)'$ and b_1 designates the first row of b . The observables (π, x) are determined as:

$$x_t = -\sigma i_t + \begin{bmatrix} \sigma & 1-\beta & -\sigma\beta \end{bmatrix} f_b + \sigma \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} (\mathbb{I}_{nx} - \beta h_x)^{-1} s_t \quad (\text{A.9})$$

$$\pi_t = \kappa x_t + \begin{bmatrix} (1-\alpha)\beta & \kappa\alpha\beta & 0 \end{bmatrix} f_a + \begin{bmatrix} 0 & 0 & 1 \end{bmatrix} (\mathbb{I}_{nx} - \alpha\beta h_x)^{-1} s_t \quad (\text{A.10})$$

B Target criterion

The target criterion in the simplified model (scalar learning of inflation intercept only, $k_t^{-1} = \mathbf{g}(f e_{t-1})$):

$$\pi_t = -\frac{\lambda_x}{\kappa} \left\{ x_t - \frac{(1-\alpha)\beta}{1-\alpha\beta} \left(k_t^{-1} + ((\pi_t - \bar{\pi}_{t-1} - b_1 s_{t-1})) \mathbf{g}_\pi(t) \right) \right. \\ \left. \left(\mathbb{E}_t \sum_{i=1}^{\infty} x_{t+i} \prod_{j=0}^{i-1} (1 - k_{t+1+j}^{-1} - (\pi_{t+1+j} - \bar{\pi}_{t+j} - b_1 s_{t+j}) \mathbf{g}_{\bar{\pi}}(t+j)) \right) \right\} \quad (\text{B.1})$$

where I'm using the notation that $\prod_{j=0}^0 \equiv 1$. For interpretation purposes, let me rewrite this as follows:

$$\pi_t = -\frac{\lambda_x}{\kappa} x_t + \frac{\lambda_x}{\kappa} \frac{(1-\alpha)\beta}{1-\alpha\beta} \left(k_t^{-1} + f e_{t|t-1}^{eve} \mathbf{g}_\pi(t) \right) \mathbb{E}_t \sum_{i=1}^{\infty} x_{t+i} \\ - \frac{\lambda_x}{\kappa} \frac{(1-\alpha)\beta}{1-\alpha\beta} \left(k_t^{-1} + f e_{t|t-1}^{eve} \mathbf{g}_\pi(t) \right) \left(\mathbb{E}_t \sum_{i=1}^{\infty} x_{t+i} \prod_{j=0}^{i-1} (k_{t+1+j}^{-1} + f e_{t+1+j|t+j}^{eve} \mathbf{g}_{\bar{\pi}}(t+j)) \right) \quad (\text{B.2})$$

Interpretation: **tradeoffs from discretion in RE** + **effect of current level and change of the gain on future tradeoffs** + **effect of future expected levels and changes of the gain on future tradeoffs**

C Impulse responses to iid monpol shocks across a wide range of learning models

$T = 400, N = 100, n_{drop} = 5$, shock imposed at $t = 25$, calibration as above, Taylor rule assumed to be known, PLM = learn constant only, of inflation only.

Figure 14: IRFs and gain history (sample means)
