

Monetary Policy & Anchored Expectations

An Endogenous Gain Learning Model

Preliminary and Incomplete

Laura Gáti

July 25, 2020

Abstract

This paper analyzes optimal monetary policy in a behavioral model where expectation formation is characterized by potential anchoring of expectations. Expectations are anchored when in an adaptive learning setting, the private sector chooses a decreasing learning gain. Within the context of an otherwise standard macro model with nominal rigidities and natural-rate and cost-push shocks, I find that the anchoring mechanism introduces two new intertemporal tradeoffs: a stabilization and a volatility tradeoff. Optimal policy is thus time-varying in two ways. First, the anchoring expectation formation allows the central bank to postpone current intratemporal tradeoffs to the future. Second, while concerns for stabilization lead the central bank to seek to anchor expectations in the long run, getting them anchored is costlier the more current expectations are unanchored. As my estimate of the anchoring function shows, forecast errors over 1 percentage points are sufficient to unanchor expectations. For this reason, the bank raises the interest rate by 0.4547 pp for a positive forecast error of 1 pp.

1 Introduction

I must - and I do - take seriously the risk that inflation shortfalls that persist even in a robust economy could precipitate a difficult-to-arrest downward drift in inflation expectations. At the heart of [our] review is the evaluation of potential changes to our strategy designed to strengthen the credibility of our [...] 2 percent inflation objective [such that] inflation expectations [remain] well anchored.

Jerome Powell, Chairman of the Federal Reserve ¹

In his opening remarks to the Federal Reserve’s recent review of its policy tools, Fed Chairman Jerome Powell echoes the common sentiment among central bankers that anchoring inflation expectations is “at the heart” of monetary policy. Yet the leading macroeconomic models of monetary policy are based on the assumption of model-consistent expectations. This assumption, often termed “rational expectations” (RE), does not capture unanchored expectations because expectations of long-run variables are by assumption equal to their steady state values - indeed, the steady state values “anchor” expectations.

But a look at the data reveals that expectations of long-run inflation move around a lot, and, in particular, may not always be anchored at the steady state target of 2%.² Fig. 1 portrays this series for the last decade in the US. As the figure shows, long-run inflation expectations of the public, averaging a little above the 2% target prior to 2015, display a marked downward drift since 2015.

Figure 1: Market-based inflation expectations, 10 year, average, %

This paper addresses the need for a theory of optimal monetary policy in an environment where expectations may become unanchored. In my behavioral model of expectation formation, the notion of anchoring is the stability of the private sector’s expectations of mean inflation over the long run. As in

¹Federal Reserve “Conference on Monetary Policy Strategy, Tools, and Communications Practices,” June 4, 2019, Opening Remarks.

²By “expectations of long-run inflation” I mean the private sector’s expectation of where inflation will be on average over a longer period in the future. Therefore I also refer to this as “expected mean inflation.”

Carvalho et al. (2019), whether expectations are anchored or not depends on the size of the learning gain, the weight that the public places on current forecast errors when updating its expectation of mean inflation. Since the size of the gain depends on forecast errors, the central bank's interest-rate setting interacts with expectation formation, leading to anchoring or unanchoring of expectations.

The main contribution of the paper is to investigate how the anchoring expectation formation affects the optimal conduct of monetary policy. For this end, I first infer the functional form of the anchoring function - the relationship between forecasting errors and learning gain - from data. I subsequently solve the Ramsey problem of the central bank in the model of anchoring to present the properties of optimal monetary policy analytically. Due to the endogeneity of the gain, the problem of finding the optimal interest rate setting of the central bank is nonlinear. I therefore rely on global methods to solve for the optimal policy function numerically.

The key takeaway is that monetary policy faces an intertemporal volatility tradeoff due to the anchoring mechanism. Because of the positive feedback between expectations and observables, anchored expectations yield lower economic volatility than unanchored ones do. But because long-run expectations move more when expectations are unanchored, an aggressive interest rate response meant to anchor expectations induces heightened short-run volatility. Therefore the central bank prefers to avoid unanchoring expectations in the first place, and reacts aggressively to subdue any potential unanchoring. For this reason, to an econometrician estimating central bank behavior using a Taylor-type rule, optimal monetary policy in the anchoring model would appear as a rule with time-varying coefficients.

To put numbers on this, the estimation reveals that already forecast errors above 1 percentage point are sufficient to unanchor expectations. Thus, for a positive forecast error of 1 pp, the optimal policy involves raising the interest rate by 0.4547 pp.

The remaining results can be summarized as follows. First, the analytical results show that the optimal Ramsey policy follows a targeting rule that spells out how the intratemporal tradeoff between inflation and unemployment is complimented by novel intertemporal tradeoffs due to the anchoring expectation formation. The extent of these tradeoffs is determined by the current and expected future stance of anchoring.

The second analytical result is a reminder that without the rational expectations assumption, many widely assumed properties of monetary models vanish. In particular, unlike time-zero optimal commitment under rational expectations, optimal policy will be time-consistent in the sense of Kydland and Prescott (1977). But not only that. Optimal policy in the anchoring model is not history-dependent: the commitment and discretion solutions of the Ramsey problem are indistinguishable because lagged multipliers are absent from the solution. Intuitively, expectation formation based on past data cannot incorporate promises on the part of the policymaker regarding the course of future policy.

Interestingly, this means that the novel intertemporal tradeoff due to anchoring alleviates the intratemporal tradeoff between inflation and the output gap. From this standpoint, it is therefore not unambiguously desirable to anchor expectations because as long as the private sector is learning, the presence of the intertemporal tradeoff allows the central bank to postpone the current intratemporal tradeoff to the future. On the other hand, unanchored expectations however imply faster learning and thus faster convergence, eliminating the intertemporal margin.

A third set of results characterizes the interest rate sequence that implements the optimal Ramsey policy. Due to the nonlinearity introduced by the endogenous gain, I use a parameterized expectations approach to solve for the optimal interest rate sequence numerically. Moreover, I approximate the optimal policy function using a cubic spline interpolant. The nonmonotonicity of the optimal policy function underscores how optimal policy seeks to suppress any potential anchoring before it materializes.

A last result pertains to the choice of optimal coefficients when monetary policy is constrained to follow a Taylor rule. It turns out that if the Taylor rule coefficients are time-invariant, monetary policy is optimally less aggressive on inflation than under rational expectations. This also relates to the intertemporal tradeoff between the volatility costs and benefits of anchoring. The restriction to constant coefficients means that the central bank must choose the same responsiveness to shocks regardless of the stance of anchoring. Forced to take an average, it opts to cause less volatility in the short-run by interfering less with the course of the economy.

Overall, my work uncovers that in the presence of expectations that can become unanchored, the monetary authority needs to monitor the evolution of long-run expectations and adjust its policy instrument in accordance with their stance. In particular, the central bank needs to act aggressively if it perceives signs of potential unanchoring to foreclose long-run expectations drifting away from the bank's target. This way, it can maintain the low-volatility benefits of having anchored expectations.

The model I use to study the interaction between monetary policy and anchoring is a behavioral version of the standard New Keynesian (NK) model of the type widely used for monetary policy analysis. Monetary policy in the rational expectations version of this model has been studied extensively, for example in [Clarida et al. \(1999\)](#) or [Woodford \(2011\)](#), whose exposition I follow. The formulation of a target criterion to implement optimal policy is in the tradition of [Svensson \(1999\)](#).

The behavioral part of the model is the departure from rational expectations on the part of the public sector. Instead, I allow the public sector to form expectations via an adaptive learning scheme, where the learning gain - the parameter governing the extent to which forecasting rules are updated - is endogenous. The learning framework belongs to the statistical learning literature advocated in the book by [Evans and Honkapohja \(2001\)](#). This literature replaces the rational expectations assumption by postulating an ad-hoc forecasting rule, the perceived law of motion (PLM), as the expectation-formation process. Agents use the PLM to form expectations and update it in every period using recursive estimation techniques. My contribution to this literature is to study optimal monetary policy in a learning model with an endogenous gain.

Adaptive learning is an attractive alternative to rational expectations for several reasons. The first reason is that it is intuitive to think that individuals in the economy do not know the true underlying model. Economists do not know the true model of the economy, so why should firms and households? And just like an econometrician estimates statistical models to form forecasts of relevant variables, it is reasonable to suppose that the private sector does so too. In fact, the anchoring expectation formation in this paper allows the private sector not only to estimate a simple statistical model, but also to adapt its forecasting model according to the volatility of the economic environment.

Secondly, many studies document the ability of adaptive learning models to match properties of expectations data and of macro aggregates. First and foremost, [Milani \(2007\)](#) demonstrates that estimated

constant gain learning models match the persistence of inflation without recourse to backward-looking elements in the Phillips curve. Eusepi and Preston (2011) show how a calibrated adaptive learning version of the real business cycle (RBC) model outperforms the rational expectations version. In particular, the learning model leads to persistent and hump-shaped responses to iid shocks, resolving the long-standing critique of RBC models of Cogley and Nason (1993). Having an endogenous gain improves the empirical properties of adaptive learning models further. Milani (2014) documents that endogenous gain models can generate endogenous time-varying volatility in models without any exogenous time-variance. Lastly, most related to my work is the paper by Carvalho et al. (2019) that estimates the evolution of the endogenous gain for the last fifty years in the US. Not only does the model display excellent out-of-sample forecasting performance in terms of matching long-run expectations, but the gain time series invites a reinterpretation of the Great Inflation as a period of unanchored expectations. Carvalho et al. (2019) thus provide empirical backing to the ideas popularized by Sargent (1999) that the conquest of American inflation consisted of anchoring inflation expectations.

The paper is structured as follows. Section 2 introduces the model. Section 3 describes the learning framework and spells out the anchoring mechanism. Section 4 estimates the anchoring function. Section 5 presents the results in three parts. First, Section 5.1 discusses an analytical characterization of the Ramsey policy. Second, Section 5.2 solves for the interest rate sequence that implements the optimal Ramsey allocation using global methods. Third, Section 5.3 investigates the optimal choice of response coefficients if monetary policy is restricted to follow a Taylor rule. Section 6 concludes.

2 The model

Apart from expectation formation, the model is a standard New Keynesian model with nominal frictions à la Calvo (1983). The advantage of having a standard NK backbone to the model is that one can neatly isolate the way the anchoring mechanism alters the behavior of the model. Since the mechanics of the rational expectations version of this model are well understood, I only lay out the model briefly and pinpoint the places where the assumption of nonrational expectations matters.³

2.1 Households

The representative household is infinitely-lived and maximizes expected discounted lifetime utility from consumption net of the disutility of supplying labor hours:

$$\hat{\mathbb{E}}_t \sum_{T=t}^{\infty} \beta^{T-t} \left[U(C_T^i) - \int_0^1 v(h_T^i(j)) dj \right] \quad (1)$$

$U(\cdot)$ and $v(\cdot)$ denote the utility of consumption and disutility of labor respectively and β is the discount factor of the household. $h_t^i(j)$ denotes the supply of labor hours of household i at time t to the production of good j , and the household participates in the production of all goods j . Similarly, household i 's

³For the specifics of the NK model the reader is referred to Woodford (2011).

consumption bundle at time t , C_t^i , is a Dixit-Stiglitz composite of all goods in the economy:

$$C_t^i = \left[\int_0^1 c_t^i(j)^{\frac{\theta-1}{\theta}} dj \right]^{\frac{\theta}{\theta-1}} \quad (2)$$

$\theta > 1$ is the elasticity of substitution between the varieties of consumption goods. Denoting by $p_t(j)$ the time- t price of good j , the aggregate price level in the economy can then be written as

$$P_t = \left[\int_0^1 p_t(j)^{1-\theta} dj \right]^{\frac{1}{\theta-1}} \quad (3)$$

The budget constraint of household i is given by

$$B_t^i \leq (1 + i_{t-1})B_{t-1}^i + \int_0^1 w_t(j)h_t^i(j) + \Pi_t^i(j)dj - T_t - P_t C_t^i \quad (4)$$

where $\Pi_t^i(j)$ denotes profits from firm j remitted to household i , T_t taxes, and B_t^i the riskless bond purchases at time t .⁴

The only difference to the standard New Keynesian model is the expectations operator, $\hat{\mathbb{E}}$. This is the subjective expectations operator that differs from its rational expectations counterpart, \mathbb{E} , in that it does not encompass knowledge of the model. In particular, households have no knowledge of the fact that they are identical. By extension, they also do not internalize that they hold identical beliefs about the evolution of the economy. As we will see in Section 2.3, this has implications for their forecasting behavior and will result in decision rules that differ from those of the rational expectations version of the model.

2.2 Firms

Firms are monopolistically competitive producers of the differentiated varieties $y_t(j)$. The production technology of firm j is $y_t(j) = A_t f(h_t(j))$, whose inverse, $f^{-1}(\cdot)$, signifies the amount of labor input. Noting that A_t is the level of technology and that $w_t(j)$ is the wage per labor hour, firm j profits at time t can be written as

$$\Pi_t^j = p_t(j)y_t(j) - w_t(j)f^{-1}(y_t(j)/A_t) \quad (5)$$

Firm j 's problem then is to set the price of the variety it produces, $p_t(j)$, to maximize the present discounted value of profit streams

$$\hat{\mathbb{E}}_t \sum_{T=t}^{\infty} \alpha^{T-t} Q_{t,T} \left[\Pi_T^j(p_T(j)) \right] \quad (6)$$

⁴For ease of exposition I have suppressed potential money assets here. This has no bearing on the model implications since it represents the cashless limit of an economy with explicit money balances.

subject to the downward-sloping demand curve

$$y_t(j) = Y_t \left(\frac{p_t(j)}{P_t} \right)^{-\theta} \quad (7)$$

where

$$Q_{t,T} = \beta^{T-t} \frac{P_t U_c(C_T)}{P_T U_c(C_t)} \quad (8)$$

is the stochastic discount factor from households. Nominal frictions enter the model through the parameter α in Equation (6). This is the Calvo probability that firm j is not able to adjust its price in a given period.

Analogously to households, the setup of the production side of the economy is standard up to the expectation operator. Also here the rational expectations operator \mathbb{E} has been replaced by the subjective expectations operator $\hat{\mathbb{E}}$. This implies that firms, like households, do not know the model equations and fail to internalize that they are identical. Thus their decision rules, just like those of the households, will be distinct from their rational expectations counterparts.

2.3 Aggregate laws of motion

The model solution procedure entails deriving first-order conditions, taking a loglinear approximation around the nonstochastic steady state and imposing market clearing conditions to reduce the system to two equations, the New Keynesian Phillips curve (NKPC) and IS curve (NKIS). The presence of subjective expectations, however, implies that firms and households are not aware of the fact that they are identical. Thus, as [Preston \(2005\)](#) points out, imposing market clearing conditions in the expectations of agents is inconsistent with the assumed information structure.⁵

Instead, I prevent firms and households from internalizing market clearing conditions.⁶ As [Preston \(2005\)](#) demonstrates, this leads to long-horizon forecasts showing up in firms' and households' first-order conditions. As a consequence, instead of the familiar expressions, the NKIS and NKPC take the following form:

$$x_t = -\sigma i_t + \hat{\mathbb{E}}_t \sum_{T=t}^{\infty} \beta^{T-t} ((1-\beta)x_{T+1} - \sigma(\beta i_{T+1} - \pi_{T+1}) + \sigma r_T^n) \quad (9)$$

$$\pi_t = \kappa x_t + \hat{\mathbb{E}}_t \sum_{T=t}^{\infty} (\alpha\beta)^{T-t} (\kappa\alpha\beta x_{T+1} + (1-\alpha)\beta\pi_{T+1} + u_T) \quad (10)$$

⁵The target of [Preston \(2005\)](#)'s critique is the Euler-equation approach as exemplified for example by [Bullard and Mitra \(2002\)](#). This approach involves writing down the loglinearized first-order conditions of the model, and simply replacing the rational expectations operators with subjective ones. In a separate paper, I demonstrate that the Euler-equation approach is not only inconsistent on conceptual grounds as [Preston \(2005\)](#) shows, but also delivers substantially different quantitative dynamics in a simulated New Keynesian model. Thus relying on the Euler-equation approach when investigating the role of learning is not only incorrect in terms of microfoundations, but also leads to mistaken quantitative inferences. In the context of this model, the problem becomes more acute when expectations are unanchored.

⁶There are several ways of doing this. An alternative to [Preston \(2005\)](#)'s long-horizon approach pursued here is the shadow price learning framework advocated by [Evans and McGough \(2009\)](#).

Here x_t , π_t and i_t are the log-deviations of the output gap, inflation and the nominal interest rate from their steady state values, and σ is the intertemporal elasticity of substitution.⁷ The variables r_t^n and u_t are exogenous disturbances representing a natural rate shock and a cost-push shock respectively.

The laws of motion (9) and (10) are obtained by deriving individual firms' and households' decision rules, which involve long-horizon expectations, and aggregating across the cross-section. Importantly, agents in the economy have no knowledge of these relations since they do not know that they are identical and thus are not able to impose market clearing conditions required to arrive at (9) and (10). Thus, although the evolution of the observables (π, x) is governed by the exogenous state variables (r^n, u) and long-horizon expectations via these two equations, agents in the economy are unaware of this. As I will spell out more formally in Section 3, it is indeed the equilibrium mapping between states and jump variables the agents are attempting to learn.⁸

To simplify notation, I gather the exogenous state variables in the vector s_t and observables in the vector z_t as

$$s_t = \begin{bmatrix} r_t^n \\ \bar{i}_t \\ u_t \end{bmatrix} \quad z_t = \begin{bmatrix} \pi_t \\ x_t \\ i_t \end{bmatrix} \quad (11)$$

where \bar{i}_t is a shock to the interest rate that only shows up in the model for particular specifications of monetary policy.⁹ This allows me to denote long-horizon expectations by

$$f_{a,t} \equiv \hat{\mathbb{E}}_t \sum_{T=t}^{\infty} (\alpha\beta)^{T-t} z_{T+1} \quad f_{b,t} \equiv \hat{\mathbb{E}}_t \sum_{T=t}^{\infty} (\beta)^{T-t} z_{T+1} \quad (12)$$

As detailed in App. A, one can use this notation to reformulate the laws of motion of jump variables (Equations (9), (10) and (26)) compactly as

$$z_t = A_a f_{a,t} + A_b f_{b,t} + A_s s_t \quad (13)$$

where the matrices A_i , $i = \{a, b, s\}$ gather coefficients and are given in App. A. Assuming that exogenous variables evolve according to independent AR(1) processes, I write the state transition matrix equation as

$$s_t = h s_{t-1} + \epsilon_t \quad \epsilon_t \sim \mathcal{N}(\mathbf{0}, \Sigma) \quad (14)$$

where h gathers the autoregressive coefficients ρ_j , ϵ_t the Gaussian innovations ε_t^j , and η the standard deviations σ_t^j , for $j = \{r, i, u\}$. $\Sigma = \eta\eta'$ is the variance-covariance matrix of disturbances.¹⁰

⁷I am using standard CRRA utility of the form $U(c_t) = \frac{c_t^{1-\sigma}}{1-\sigma}$.

⁸The learning of (9) and (10) is complicated by the fact that the current stance of expectations figures into the equations, resulting in the well-known positive feedback effects of learning.

⁹For generality, I treat the exogenous state vector as three-dimensional throughout the paper, even when the monetary policy shock is absent.

¹⁰For the sake of conciseness, I have suppressed the expressions for these in the main text. See App. A.

3 Learning with an anchoring mechanism

The informational assumption of the model is that agents have no knowledge of the equilibrium mapping between states and jumps in the model. Without knowing the form of the observation equation, then, they are not able to form rational expectations forecasts.¹¹ Instead, agents postulate an ad-hoc forecasting relationship between states and jumps and seek to refine it in light of incoming data. In other words, they act like an econometrician: they estimate a simple statistical model and attempt to improve the fit of their model.

3.1 Perceived law of motion

I assume agents consider a forecasting model for jumps of the form

$$\hat{\mathbb{E}}_t z_{t+1} = a_{t-1} + b_{t-1} s_t \quad (15)$$

where a and b are estimated coefficients of dimensions 3×1 and 3×3 respectively. This perceived law of motion (PLM) reflects the assumption that agents forecast jumps using a linear function of current states and a constant, with last period's estimated coefficients. Summarizing the estimated coefficients as $\phi_{t-1} \equiv \begin{bmatrix} a_{t-1} & b_{t-1} \end{bmatrix}$, here 3×4 , I can rewrite Equation (15) as

$$\hat{\mathbb{E}}_t z_{t+1} = \phi_{t-1} \begin{bmatrix} 1 \\ s_t \end{bmatrix} \quad (16)$$

I also assume that

$$\hat{\mathbb{E}}_t \phi_{t+k} = \phi_t \quad \forall k \geq 0 \quad (17)$$

This assumption, known in the learning literature as anticipated utility, means that agents fail to internalize that they will update the forecasting rule in the future. This is the most behavioral element in the expectation-formation process since it postulates that agents think differently about their own behavior than how they actually act. Clearly, this poses a higher level of irrationality than not knowing the model and using statistical techniques to attempt to learn it. Because it has been demonstrated not to alter the dynamics of the model (Sargent (1999)), anticipated utility has become a standard assumption in the adaptive learning literature in order to simplify the algebra.

Assuming that agents know the evolution of states, that is they have knowledge of Equation (14)¹²,

¹¹To see this, observe that an agent with rational expectations would internalize all of the rational expectations state-space system. Therefore, she would use the state transition equation (14) together with the observation equation (B.1) in App. B to forecast future jumps as $\mathbb{E}_t z_{t+k} = g^{RE} \mathbb{E}_t s_{t+k} = g^{RE} h^k s_t$, where g^{RE} is the mapping between states and jumps under rational expectations. Agents in the learning model however do not know (B.1) and are thus indeed unable to form the rational expectations forecast.

¹²This is another common simplifying assumption in studies of adaptive learning. In an extension, I relax this assumption and find that it has similar implications as having agents learn the Taylor rule: initial responses to shocks lack intertemporal expectation effects, but these reemerge as the evolution of state variables is learned.

the PLM together with anticipated utility implies that k -period ahead forecasts are constructed as

$$\hat{\mathbb{E}}_t z_{t+k} = a_{t-1} + b_{t-1} h^{k-1} s_t \quad \forall k \geq 1 \quad (18)$$

The timing assumptions of the model are as follows. In the beginning of period t , the current state s_t is realized. Agents then form expectations according to (15) using last period's estimate ϕ_{t-1} and the current state s_t . Given exogenous states and expectations, today's jump vector z_t is realized. This allows agents to evaluate the most recent forecast error $f_{e_{t|t-1}} \equiv z_t - \phi_{t-1} \begin{bmatrix} 1 \\ s_{t-1} \end{bmatrix}$ to update their forecasting rule. The estimate is updated according to the following recursive least-squares algorithm:

$$\phi_t = \left(\phi'_{t-1} + k_t R_t^{-1} \begin{bmatrix} 1 \\ s_{t-1} \end{bmatrix} \left(z_t - \phi_{t-1} \begin{bmatrix} 1 \\ s_{t-1} \end{bmatrix} \right)' \right)' \quad (19)$$

$$R_t = R_{t-1} + k_t \left(\begin{bmatrix} 1 \\ s_{t-1} \end{bmatrix} \begin{bmatrix} 1 & s_{t-1} \end{bmatrix} - R_{t-1} \right) \quad (20)$$

where R_t is the 4×4 variance-covariance matrix of the regressors and k_t is the learning gain, specifying to what extent the updated estimate loads on the forecast error. Clearly, a high gain implies high loadings and thus strong changes in the estimated coefficients ϕ_t . A low gain, by contrast, means that the current forecast error only has a small effect on ϕ_t .

3.2 Endogenous gain as anchoring mechanism

The vast majority of the learning literature specifies the gain either as a constant, \bar{g} , or decreasing with time, so that $k_t = (k_{t-1}^{-1} + 1)^{-1}$. Instead, to capture the notion of anchoring, I follow [Carvalho et al. \(2019\)](#) to allow firms and households in the model to choose the value of the gain. I use the following endogenous gain specification: let $f_{e_{t|t-1}}$ denote the forecast error of time t variables given information at $t-1$. Then the gain evolves as

$$k_t = \mathbf{g}(k_{t-1}, f_{e_{t|t-1}}) \quad (21)$$

where $\mathbf{g}(\cdot)$ is a smooth, increasing function in both arguments that I refer to as the anchoring function. App. C compares alternative specifications for $\mathbf{g}(\cdot)$ and discusses the motivation behind using specific functional forms.¹³ I let my choice of functional form for $\mathbf{g}(\cdot)$ be guided by data, wherefore I start my inquiry by estimating the anchoring function (see Section 4).

Having an endogenous gain has the interpretation of agents being able to adapt their forecasting behavior to the volatility of their environment. For a given previous gain, if agents observe small forecast errors, $\mathbf{g}(\cdot)$ is small. Firms and households thus use a small gain to update their forecasting rule, reflecting their belief that the underlying data-generating process (DGP) has not changed compared to their earlier held beliefs. I refer to this case as *anchored expectations* because it captures the notion

¹³Equation (21) nests decreasing gains or constant gains as special cases. In both cases, the derivative of the anchoring function with respect to its second argument is 0, but a decreasing gain implies $\mathbf{g}(k_{t-1}, f_{e_{t|t-1}}) = (k_{t-1}^{-1} + 1)^{-1}$, while a constant gain sets $\mathbf{g}(k_{t-1}, f_{e_{t|t-1}}) = \bar{g}$.

that the private sector's long-run expectations of the observables are stable.

By contrast, observing large forecast errors leads to $\mathbf{g}(\cdot)$ being sufficiently large so that the gain increases. This corresponds to assigning a higher weight to more recent observations than old ones. Such a forecasting scheme outperforms a lower gain scheme when the environment is volatile, reflecting a possible regime switch. If the previous DGP has been replaced by a new one, having a high gain allows agents to discount old observations generated by the previous DGP, and rely more on the newest observations that come from the current DGP. In this way, agents can learn the new DGP faster, correcting their previously held long-run expectations. This is the case of *unanchored expectations*, and it induces long-run expectations to drift away from their previous values.

It is intuitive why the central bank might care whether expectations are anchored or not. When expectations are unanchored at time t , the private sector believes that the true DGP involves a different mapping between states and jumps than they previously maintained. Private sector forecasts will thus drift in the direction of the update, implying that the observables will also shift in the same direction owing to the law of motion (13). From the perspective of the central bank, stabilization of the observables therefore implies stabilization of expectations. However, it is not obvious that the central bank prefers to anchor expectations at all points in time because regime shifts in model parameters might warrant letting the private sector learn the new DGP fast. Indeed, the contribution of this paper is to characterize formally the nature of the monetary policy problem when expectation formation is characterized by the anchoring mechanism.

3.3 Actual law of motion

To complete the model, I now use the specifics of the anchoring expectation formation to characterize the evolution of the jump variables under learning. Using the PLM from Equation (15), I write the long-horizon expectations in (12) as

$$f_{a,t} \equiv \frac{1}{1 - \alpha\beta} a_{t-1} + b_{t-1} (I_3 - \alpha\beta h)^{-1} s_t \quad f_{b,t} \equiv \frac{1}{1 - \beta} a_{t-1} + b_{t-1} (I_3 - \beta h)^{-1} s_t \quad (22)$$

Substituting these into the law of motion of observables (Equation (13)) yields the actual law of motion (ALM):

$$z_t = g_{t-1}^l \begin{bmatrix} 1 \\ s_t \end{bmatrix} \quad (23)$$

where g^l is a 3×4 matrix given in App. B. Thus, instead of the state-space solution of the RE version of the model (Equations (14) and (B.1)), the state-space solution for the learning model is characterized by the pair of equations (14) and (23).

4 Estimating the anchoring function

The numerical analysis of monetary policy requires a functional specification for the anchoring function $\mathbf{g}(\cdot)$ of Equation (21). But one may be interested in the form of the anchoring function in its own right

because it carries the answer to a question crucial to central bankers: for what sign and size forecast errors do expectations become unanchored?

Because the analytical results in Section 5.1 are based on a specification of the gain as a function of forecast errors only, I here present estimation results for that restricted specification.¹⁴ Since the shape of the anchoring function is meaningful, I employ a piecewise linear approximation of the form:

$$\mathbf{g}(fe_{t|t-1}) = \alpha b(fe_{t|t-1}) \quad (24)$$

where $b(\cdot)$ is a second order spline basis and α is a vector of approximating coefficients. I estimate α by simulated method of moments à la Lee and Ingram (1991), Duffie and Singleton (1990) and Smith (1993). I target the autocovariance structure of CPI inflation from the Bureau of Labor Statistics (BEA), the output gap, the federal funds rate from the Board of Governors of the Federal Reserve System and 12-month-ahead inflation forecasts from the Survey of Professional Forecasters (SPF).¹⁵ The dataset is quarterly and ranges from 1980-Q3 to 2020-Q1. App. D contains a detailed description of the estimation methodology.

Figure 2: Estimated $\hat{\alpha}$: k_t as a function of $fe_{t|t-1}$

Estimates for $N = 1000$, imposing convexity with weight 100000, truth with $nfe = 5$, $fe \in (-2, 2)$

Fig. 2 presents the estimated coefficients. The interpretation of the elements of $\hat{\alpha}$ is the value of the gain the private sector chooses when it observes a forecast error of a particular magnitude. For example, a forecast error of -2 pp in inflation is associated with a gain of 0.0257. Thus, the data suggest that small forecast errors, below 1 pp in magnitude, do not unanchor expectations as the corresponding gain is very small, below 0.01. Above 1 pp, however, the gain increases rapidly.

What amounts to a large gain? The consensus in the literature on estimating learning gains lies between 0.01-0.05. On the higher end, Branch and Evans (2006) estimate a constant gain on inflation of 0.062. Milani (2007) finds 0.0183. The estimates of the maximal value for endogenous gains lie

¹⁴Estimates of the general functional form are available on request.

¹⁵The output gap measure is constructed as the difference between real GDP from the Bureau of Economic Analysis (BEA) and the Congressional Budget Office's (CBO) estimate of real potential output.

somewhat higher, at 0.082 in Milani (2014) and at 0.145 in Carvalho et al. (2019). Calibrated models tend to use the consensus values between 0.01-0.05, however, Eusepi and Preston (2011) found that the value of 0.002 was sufficient to significantly alter the dynamic behavior of their RBC model.

An intuitive interpretation of the gain is that its inverse gives the number of past observations the private sector uses to form its current forecasts. My minimum value, 0.005, thus implies that firms and households, if they see no forecast errors, rely on the last 50 years of data.¹⁶ By contrast, forecast errors of 2 pp in absolute value lead to a number around 0.03, which means that agents discount any observations older than about 8 years. That is not a long time horizon; for a household or firm using a gain of 0.03 today, this would imply that the Great Recession is no longer in its dataset.

Taken together, this allows me to interpret forecast errors exceeding 1 pp as threatening to unanchor, and forecast errors in the range of 2 pp as substantially unanchoring expectations. In particular, the private sector begins suspecting that a regime change may have occurred as soon as it sees that its forecasting procedure missed inflation by 1 pp.

5 Monetary policy and anchoring

This section sets up and solves the optimal monetary policy problem in the model with the anchoring expectation formation. In Section 5.1, I begin by analyzing the Ramsey problem of determining optimal paths for the endogenous variables that policy seeks to bring about. While the anchoring mechanism introduces substantial nonlinearity into the model, it is possible to derive analytically an optimal target criterion for the policymaker to follow. As we shall see, the optimal rule prescribes for monetary policy to act conditionally on the stance of expectations, and will thus be time-varying. In particular, whether expectations are anchored or not matters for the extent to which there is a tradeoff between inflation and output gap stabilization, and also for the volatility cost of getting expectations anchored.

I then turn to the question of how to implement optimal policy. Section 5.2 uses global methods to solve for the interest rate sequence that implements the target criterion. The optimal sequence is contrasted with a Taylor rule with standard parameters. I then discuss the properties that the optimal interest rate policy should have.

Since history-dependence is not a feature of the optimal solution, purely forward-looking Taylor rules are no longer excluded from the class of rules that can implement the Ramsey solution. In Section 5.3, I therefore restrict attention to Taylor-type feedback rules for the interest rate. I solve for the optimal Taylor-rule coefficients numerically and investigate how the choice of Taylor-rule coefficients affects the anchoring mechanism. In contrast to conventional wisdom in learning models, optimal monetary policy is *less* aggressive on inflation (and on the output gap) in the anchoring model than under rational expectations. As I explain in detail, the reason is that while having anchored expectations is beneficial in order to lower economic volatility in the long run, in the short run it is costly to get expectations anchored. It is also a residue of the fact that the exercise constrains the Taylor-rule coefficients to be time-invariant, whereas optimal policy, as we will see, is time-varying.

¹⁶The frequency of the model and the data is quarterly.

5.1 The Ramsey policy under anchoring

I assume the monetary authority seeks to maximize welfare of the representative household under commitment. As shown in [Woodford \(2011\)](#), a second-order Taylor approximation of household utility delivers a central bank loss function of the form

$$L^{CB} = \mathbb{E}_t \sum_{T=t}^{\infty} \{ \pi_T^2 + \lambda_x (x_T - x^*)^2 + \lambda_i (i_T - i^*) \} \quad (25)$$

where λ_j $j = \{x, i\}$ is the weight the central bank assigns to stabilizing variable j and j^* is its target value.¹⁷ The central bank's problem, then, is to determine paths for inflation, the output gap and the interest rate that minimize the loss in Equation (25), subject to the model equations (9) and (10), as well as the evolution of long-horizon expectations, spelled out in Section 3. A second question is how to implement the optimal allocation; that is, to find a response function for the policy instrument i_t that implements the optimal sequences of the observables.

While for most of the paper I consider a general specification for monetary policy, in Section 5.3, I will restrict attention to a standard Taylor rule:

$$i_t = \psi_\pi (\pi_t - \pi^*) + \psi_x (x_t - x^*) + \bar{i}_t \quad (26)$$

where ψ_π and ψ_x represent the responsiveness of monetary policy to inflation and the output gap respectively, π^* and x^* are the central bank's targets. Lastly, \bar{i}_t is a monetary policy shock. I also assume that when the Taylor rule is in effect, the central bank publicly announces this. Thus Equation (26) is common knowledge and is therefore not the object of learning.¹⁸

5.1.1 Optimal Ramsey policy as a target criterion

Appendix E lays out the policy problem for a simplified version of the baseline model. It also depicts how the endogeneity of the gain introduces nonlinearity into the model. This prevents an analytical solution to the Ramsey problem. Instead, I characterize the first-order conditions of the problem analytically, and proceed in Section 5.2 to solve the full problem numerically.

To simplify the analytical treatment, I make three additional assumptions compared to the baseline model. First, I assume that only the inflation process is learned; expectations about the output gap and the interest rate are rational evaluations of the infinite sum of future expectations.¹⁹ Second, I assume that only the constant of the inflation process is learned. Third, I consider a specification of the anchoring function where the current gain depends on the most recent forecast error only:²⁰

¹⁷To be precise, the second-order approximation to household utility involves $\lambda_i = 0$. In practice, $\lambda_i > 0$ is often assumed to avoid an optimal interest rate path with infinitely large fluctuations.

¹⁸In an extension I consider the case where the Taylor rule is not known (or not believed) by the public and therefore is learned together with the relations (9) and (10). This dampens intertemporal expectation effects as long as the Taylor rule is not learned; afterwards, the model dynamics are identical to those of the baseline.

¹⁹By "rational" I here mean the expectations that agents would hold in the rational expectations equilibrium (REE). Because the model is not in the REE, these "rational" expectations are not model-consistent.

²⁰These assumptions are made for algebraic convenience only and do not alter the qualitative implications of the model.

$$k_t = \mathbf{g}(f_{e_t|t-1}) \quad (27)$$

The solution of the Ramsey problem under these assumptions is stated in the following result.

Result 1. *Target criterion in the anchoring model*

The targeting rule in the simplified learning model with anchoring is given by

$$\pi_t = -\frac{\lambda_x}{\kappa}x_t + \frac{\lambda_x}{\kappa}\frac{(1-\alpha)\beta}{1-\alpha\beta}\left(k_t + f_{e_t|t-1}\mathbf{g}_{\pi,t}\right)\left(\mathbb{E}_t\sum_{i=1}^{\infty}x_{t+i}\prod_{j=0}^{i-1}(1-k_{t+1+j}-f_{e_{t+j}|t+j-1}\mathbf{g}_{\bar{\pi},t+j})\right) \quad (28)$$

$$\text{with } f_{e_{t+j}|t+j-1} = \pi_{t+1+j} - \bar{\pi}_{t+j} - b_1s_{t+j}$$

For the derivation, see Appendix E. For a general target criterion without assumption (27), see Appendix F. Note the notation that $\prod_{j=1}^0 \equiv 1$.

The interpretation of Equation (28) is that the *intratemporal* tradeoff between inflation and the output gap due to cost-push shocks is complemented by two *intertemporal* tradeoffs: one due to learning in general, and one due to anchoring in particular.

The first intertemporal effect comes from the current level of the gain, k_t , which captures how far learning is from converging to rational expectations. The second intertemporal tradeoff is manifest in the derivative of the anchoring function today, $\mathbf{g}_{\pi,t}$, as well as in all expected levels and changes in the gain in the future in the expression $(1-k_{t+j}(\pi_{t+1+j}-\bar{\pi}_{t+j}-b_1s_{t+j})\mathbf{g}_{\bar{\pi},t+j})$ in the second bracket on the right-hand side. These expressions say that the presence of anchoring amplifies the first intertemporal tradeoff because now the degree and direction in which the gain changes today and is expected to change in the future matter too. In other words, the central bank needs to consider whether its chosen interest rate sequence contributes to anchoring expectations in future periods, or whether it actually serves to unanchor them.

Let me investigate these channels in isolation. To see exactly what the role of anchoring is in the target criterion, consider first the special case of exogenous gain adaptive learning, for simplicity with a constant gain specification.²¹ In this case the anchoring function and the forecast error are irrelevant (since $\mathbf{g}_i = 0, i = \pi, \bar{\pi}$) and (28) boils down to

$$\pi_t = -\frac{\lambda_x}{\kappa}x_t + \frac{\lambda_x}{\kappa}\frac{(1-\alpha)\beta}{1-\alpha\beta}k\left(\sum_{i=1}^{\infty}x_{t+i}(1-k)^i\right) \quad (29)$$

which now is the analogue of Gaspar et al. (2010)'s Equation (24).²² This result, found also by Molnár and Santoro (2014), suggests that already the presence of learning introduces an intertemporal tradeoff between inflation and output gap stabilization. However, the fact that the central bank now has future

For analytical results for the more general version of the anchoring function, see App. F.

²¹The intuition is identical if the public were using a decreasing gain but the mathematics would not convey that same intuition as cleanly.

²²In their Handbook chapter, Gaspar et al. (2010) provide a parsimonious treatment of Molnár and Santoro (2014). I am referring to their expression for the target criterion because Molnár and Santoro (2014) do not provide one explicitly.

output gaps as a margin of adjustment means that it does not have to face the full tradeoff in the current period. Learning allows the central bank to improve the current output gap without sacrificing inflation stability today; however, this results in a worsened tradeoff in the future. In other words, adaptive learning by itself allows the central bank to postpone the current tradeoff to later periods.

Intuitively, this happens because adaptive expectations are slow in converging to rational expectations. In the transition, the private sector's expectations do not adjust to fully internalize the intratemporal tradeoff. This gives the monetary authority room to transfer the tradeoff to the future.

Contrasting Equations (29) and (28) highlights the role of anchoring. With anchoring, the extent to which policy can transfer the intratemporal tradeoff to future periods depends not only on the stance of the learning process, as in (29), but also on whether expectations are anchored or not and in which direction they are moving. In fact, not only the current stance and change of anchoring matters, but also all expected future levels and changes.

Anchoring, however, complicates the possibility of transferring today's tradeoff to the future. One can see this in the fact that forecast errors and the derivatives of the anchoring function are able to flip the sign of the second term in (28). This means that anchoring can alleviate or worsen the intertemporal tradeoff. To see the intuition, consider the equation system of first-order conditions from solving the Ramsey problem. While the full system is presented in App. E, I would like to focus on Equation (E.8), the equation governing the dynamics of observables in the model:

$$2\pi_t = -2\frac{\lambda_x}{\kappa}x_t + \varphi_{5,t}k_t + \varphi_{6,t}\mathbf{g}_{\pi,t} \quad (30)$$

The Lagrange multipliers $\varphi_5 \geq 0$ and $\varphi_6 \geq 0$ are the multipliers of the RLS updating and the anchoring function respectively. This equation, upon substitution of the solutions for the two multipliers, yields the target criterion. It is therefore easy to read off the intuition at a glance. First, since $\varphi_{5,t}k_t > 0$, one immediately obtains the above-discussed conclusion that as long as the adaptive learning equation is a constraint to the policymaker ($\varphi_{5,t} > 0$), the central bank has more room to transfer the contemporaneous tradeoff between inflation and the output gap to the future.²³

However, whether the anchoring equation alleviates or exacerbates the inflation-output gap tradeoff depends on the sign of $\mathbf{g}_{\pi,t}$. If the derivative is positive, the effect is the same as above, and the central bank has more leeway to postpone the tradeoff to the future. By contrast, if the derivative is negative, that is expectations are becoming anchored, the intratemporal tradeoff is worsened.

Why do unanchored expectations give the central bank the possibility to postpone its current inflation-output gap tradeoff? The reason is that when expectations become unanchored, the learning process is restarted. A not-yet converged learning process implies, as discussed above, that postponing

²³Strictly speaking, φ_5 and φ_6 are never zero in this model. The reason is that the anchoring model is a convex combination of decreasing and constant gain learning. The former has the RE equilibrium as a limit, while the latter fluctuates around the REE with bounded variance. In the anchoring setting, if expectations are anchored and there are no inflation surprises, the gain converges to zero and the decreasing gain limit of discretionary RE obtains. However, exogenous disturbances induce unforecastable variation, producing forecast errors that will unanchor expectations, restarting the learning process. This is in stark contrast with [Carvalho et al. \(2019\)](#), where the anchoring function is the map between the PLM and the expected ALM and thus only depends on the endogenous component of the forecast error. Therefore, in their model, absent regime switches, expectations can never become unanchored once learning has converged.

the tradeoff is possible. Restarting the convergence process thus unlocks this possibility.

This does not imply that the central bank should prefer to have unanchored expectations. In fact, the answer to whether expectations should be anchored from the viewpoint of the central bank depends on the current stance of learning. Clearly, the central bank prefers to face a learning process that on the one hand has not yet converged, and on the other is converging only slowly. A high gain under unanchored expectations implies both a sizable distance from convergence as well as faster learning and thus faster convergence. Therefore, ideally the central bank would like to have expectations anchored but the gain far from zero. Once the gain approaches zero, only unanchored expectations can raise it again to restart the learning process. But once the gain is large, the only way to slow down learning is to anchor expectations.

This reveals that unanchoring expectations can alleviate the stabilization tradeoff between inflation and the output gap. Having unanchored expectations, however, is costly. As I demonstrate in Sections 5.2-5.3, unanchored expectations lead to more volatility in the observables due to more volatile forecast errors in the wake of a higher gain. Moreover, getting unanchored expectations anchored again is also costly. Therefore heightened inflation and output gap volatility may be too high a price to pay for an ameliorated inflation-output gap tradeoff.

5.1.2 Time-consistence of optimal plans under adaptive learning

Now simplify the target criterion further, assuming that learning has converged, $k_t = \mathbf{g}_\pi = 0$. We are left with

$$\pi_t = -\frac{\lambda_x}{\kappa} x_t \quad (31)$$

which corresponds to the optimal discretionary solution for rational expectations in [Clarida et al. \(1999\)](#). This is formalized in the following result.

Result 2. *Coincidence of commitment and discretion under adaptive learning*

In an adaptive learning model with exogenous or endogenous gain, the optimal Ramsey policies under commitment and discretion coincide. The optimal Ramsey plan is more akin to discretion than to commitment as it does not involve making promises about future policy actions. Optimal policy is thus not subject to the time-inconsistency problem of [Kydlan and Prescott \(1977\)](#).

To illustrate this result in a parsimonious manner, consider a simplified version of the model. The planner chooses $\{\pi_t, x_t, f_t, k_t\}_{t=t_0}^\infty$ to minimize

$$\begin{aligned} \mathcal{L} = \mathbb{E}_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} & \left\{ \pi_t^2 + \lambda x_t^2 + \varphi_{1,t}(\pi_t - \kappa x_t - \beta f_t + u_t) \right. \\ & \left. + \varphi_{2,t}(f_t - f_{t-1} - k_t(\pi_t - f_{t-1})) + \varphi_{3,t}(k_t - \mathbf{g}(\pi_t - f_{t-1})) \right\} \end{aligned}$$

where the IS-curve, $x_t = \mathbb{E}_t x_{t+1} + \sigma f_t - \sigma i_t + \sigma r_t^n$, is a non-binding constraint, and is therefore excluded from the problem. φ_i are Lagrange-multipliers and $\mathbb{E}_t x_{t+1}$ is rational.²⁴ In this simplified setting, f_t is

²⁴Again, the use of the term “rational” in this context reflects corresponding to expectations in a REE.

a stand-in variable capturing inflation expectations and evolves according to a recursive least squares algorithm. The anchoring function $\mathbf{g}(\cdot)$ specifies how the gain k_t changes as a function of the current forecast error according to assumption (27).²⁵ Note that the problem involves commitment because the monetary authority internalizes the effects of its actions both on the evolution of expectations and on that of the gain.

After some manipulation, first-order conditions reduce to:

$$2\pi_t + 2\frac{\lambda_x}{\kappa}x_t - \varphi_{2,t}(k_t + \mathbf{g}_\pi(\pi_t - f_{t-1})) = 0 \quad (32)$$

$$-2\beta\frac{\lambda_x}{\kappa}x_t + \varphi_{2,t} - \varphi_{2,t+1}(1 - k_{t+1} - \mathbf{g}_f(\pi_{t+1} - f_t)) = 0 \quad (33)$$

Inspection of this system reveals that, unlike the rational expectations case ($f_t = \mathbb{E}_t \pi_{t+1}$), the optimal solution does not involve lagged multipliers.²⁶ This implies that the monetary authority cannot condition the optimal time path of inflation and the output gap on the past; optimal policy is not history-dependent.

The intuition for this result is easy to see if one compares rational expectations and learning in an infinitely repeated game setting. Under rational expectations, the lagged multiplier appears in the solution because expected inflation is a jump variable. This reflects that expectations fulfill a form of optimality, rendering the private sector a strategic player. The adjustment of expectations under rational expectations enables the central bank to make promises about future policy that are incorporated into expectations.

Not so for adaptive expectations. Learning agents look exclusively to past data to form expectations. Their expectations thus cannot incorporate the policymaker's promises about the future course of policy. In fact, a private sector with adaptive expectations has a pre-specified, non-strategic expectation formation. Therefore, households and firms act as an automaton, leaving the central bank unable to make promises that have any effect on expectations.²⁷

Should we be surprised that adaptive learning involves no distinction between discretion and commitment? Not at all if we recall that the rational expectations revolution had as one of its aims to remedy this feature of expectations. The seminal Lucas-critique, for instance, emphasizes that reduced-form regressions are not ideal guiding principles for policy advice precisely because they miss the time-varying nature of estimated coefficients due to model-consistent expectations that incorporate policy action (Lucas (1976)).

One might be concerned that a model of anchoring that is not immune to the Lucas-critique may not be a desirable normative model for policy. But recall that the anchoring model is a description of the economy in transition, not of one at its ergodic mean. It characterizes expectation formation en route to becoming model-consistent as the private sector learns the underlying DGP. In the long run, then,

²⁵Here I maintain assumption (27) for presentational purposes. It has no bearing on the results.

²⁶This echoes the findings of Molnár and Santoro (2014).

²⁷Mele et al. (2019) report a similar finding in a decreasing gain learning model. Their terminology of contrasting “inflation-targeting” with “price-level targeting” policy rules renders the connection to commitment less immediate, but it is helpful to recall that in the rational expectations NK model, optimal discretionary monetary policy involves inflation stabilization, while optimal commitment entails full price-level stabilization.

rational expectations offers a good characterization of the expectation formation of learning agents. It is in the short run that the predictions of the two expectations schemes differ. Data suggest that in terms of positive implications, learning models fare much better than rational expectations models do. Since the seminal work by [Coibion and Gorodnichenko \(2015\)](#), rational expectations has been rejected in numerous empirical papers. At the same time, the literature cited in the Introduction demonstrates the success of learning models to fit both the properties of expectations in the data and improve the business cycle dynamics of other model variables.

There are also avenues to address the Lucas-critique in learning models. One option is to reintroduce a sense of optimality to expectation formation directly, as in the literature on central bank reputation. (See [Cho and Matsui \(1995\)](#) and [Ireland \(2000\)](#)). Another possible remedy is to retain a sufficient degree of forward-looking expectations as in the finite-horizon planning approach advocated by [Woodford \(2019\)](#). A third possibility is to model communication by the central bank in the form of news shocks that enter the state vector, and thus show up in the information set of agents, as in [Dombeck \(2017\)](#).

5.2 Implementing the Ramsey policy: the optimal interest rate sequence

Having a characterization of optimal policy in the anchoring model as a first-order condition, the next relevant question is how the central bank should set its interest rate tool in order to implement the target criterion in (28). In other words, we would like to know what time-path of interest rates implements the optimal sequence of inflation and output gaps. As emphasized in Section 5.1, the nonlinearity of the model does not admit an analytical answer to this question. I therefore solve for the optimal interest rate policy numerically using global methods.

For the numerical approach I use the calibration of model parameters outlined in Table 1. Where possible, I adopt standard parameters from the literature. In particular, for β, σ and other parameters underlying κ , the slope of the Phillips curve, I rely on the parameterization of [Chari et al. \(2000\)](#), advocated in [Woodford \(2011\)](#).²⁸ The probability of not adjusting prices, α , is set to match an average price duration of two quarters, which is a little below the numbers found in empirical studies.²⁹ I set λ_x to 0.05, the value estimated by [Rotemberg and Woodford \(1997\)](#). A low, nonzero value for λ_x is also desirable because it implies that a concern for output gap stabilization is not the main driver of the central bank's actions, yet the right hand side of the target criterion in (28) is not trivial either.

The other motivation for the choice of some parameters is ease of interpretation. First, I restrict the shocks to be iid. Second, in sections of the paper where I assume a Taylor rule, I set a zero coefficient on the output gap, and unless otherwise specified, I set the inflation coefficient of the Taylor rule to

²⁸The composite parameter κ is given by $\kappa = \frac{(1-\alpha)(1-\alpha\beta)}{\alpha}\zeta$, where ζ is a measure of strategic complementarity in price setting. Assuming specific factor markets, constant desired markups with respect to output levels and no intermediate inputs, $\zeta = \frac{\omega+\sigma-1}{1+\omega\theta}$. Here θ is the price elasticity of demand and ω is the elasticity of the marginal cost function with respect to output. [Chari et al. \(2000\)](#)'s calibration involves $\theta = 10, \sigma = 1, \omega = 1.25, \beta = 0.99$, so that together with my choice of α , κ is pinned down.

²⁹The evidence on the average duration of prices can be summarized as follows. On the lower end, [Bils and Klenow \(2004\)](#) find a mean duration of 4.3 months and [Klenow and Malin \(2010\)](#) find 6.9 months. [Klenow and Kryvtsov \(2008\)](#) and [Nakamura and Steinsson \(2008\)](#) agree on between 7-9 months, while [Eichenbaum et al. \(2011\)](#)'s number is 10.6 months. This averages to a little above 7 months. My number for α corresponds to 6 months. I choose the lower end of this spectrum in order to allow the learning mechanism, and not price stickiness, to drive the bulk of the model's persistence.

Table 1: Calibrated parameters

| | | |
|-------------|--------|--|
| β | 0.99 | stochastic discount factor |
| σ | 1 | intertemporal elasticity of substitution |
| α | 0.5 | Calvo probability of not adjusting prices |
| κ | 0.0842 | slope of the Phillips curve |
| ψ_π | 1.5 | coefficient of inflation in Taylor rule* |
| ψ_x | 0 | coefficient of the output gap in Taylor rule* |
| \bar{g} | 0.145 | initial value of the gain |
| ρ_r | 0 | persistence of natural rate shock |
| ρ_i | 0 | persistence of monetary policy shock* |
| ρ_u | 0 | persistence of cost-push shock |
| σ_r | 1 | standard deviation of natural rate shock |
| σ_i | 1 | standard deviation of monetary policy shock* |
| σ_u | 1 | standard deviation of cost-push shock |
| λ_x | 0.05 | weight on the output gap in central bank loss |
| λ_i | 0 | weight on the interest rate in central bank loss |

1.5, the value recommended by [Taylor \(1993\)](#). Note that the asterisks in Table 1 demarcate parameters that pertain to the Taylor rule and thus only to sections of the paper which assume that a Taylor rule is in effect.

I initialize the value of the gain at $\bar{g} = 0.145$, the value for the gain corresponding to unanchored expectations estimated by [Carvalho et al. \(2019\)](#). If the anchoring function were discrete, as in [Carvalho et al. \(2019\)](#), this parameter would have important implications for model dynamics because in that case the gain is restricted to take on this value if it is nondecreasing.³⁰ However, since I rely on an approximation of a smooth anchoring function, \bar{g} does not have a strong bearing on model dynamics. The target criterion (28) requires that the derivatives of the anchoring function exist, wherefore a smooth specification makes sense. Moreover, in estimating the functional form of the anchoring rule, I allow the data to speak, thereby avoiding difficult calibration decisions.

App. G outlines my preferred solution procedure, the parameterized expectations approach, while App. H gives the details of the parametric value function iteration approach I implement as a robustness check. The main output of this procedure is an approximation of the optimal interest rate policy as a function of the vector of state variables. Since the relevant state variables are the gain, expected mean inflation and the exogenous states at time t and $t - 1$, the state vector is six-dimensional:

$$X_t = (\bar{\pi}_{t-1}, k_{t-1}, r_t^n, u_t, r_{t-1}^n, u_{t-1}) \quad (34)$$

As a first step, I plot how the approximated policy function depends on $\bar{\pi}_{t-1}$ and k_{t-1} , while keeping all the other states at their mean. One can thus interpret the result, depicted on Fig. 3, as a partial derivative of the interest rate with respect to k_{t-1} (panel (a)) and $\bar{\pi}_{t-1}$ (panel (b)) respectively.

As illustrated by Fig. 3, optimal interest-rate setting responds linearly and very sensitively to the stance of expectations, $\bar{\pi}_{t-1}$. As panel (b) suggests, if expected mean inflation drifts to just -0.05%,

³⁰See App. C for alternative specifications of the anchoring function, such as that of [Carvalho et al. \(2019\)](#).

Figure 3: Comparative statics: policy in function of the endogenous states

the interest rate drops to almost -6%! By contrast, the interest rate response to the gain in isolation is small in magnitude, on the order of 10^{-6} .

Let's put some numbers on this, recognizing the fact that the gain and expected mean inflation in the model move in tandem. Regressing $\bar{\pi}$ on k in a sample where $\bar{\pi}$ is always positive reveals that for a unit increase in the gain, the long-run inflation expectation increases by 5pp.³¹ I then compute the average uptick in k^{-1} in the sample, obtaining 0.00088981. This means that on average in the sample, expectations threaten to become unanchored by an upward shift of the gain of approximately 0.0009, which is associated with a drift in $\bar{\pi}$ of 0.0044. The optimal policy function implies an interest rate response of 0.4547 pp. The interpretation is that on average, when expectations threaten to become unanchored upward, the central bank should raise the interest rate by 0.4547 pp.³² This is a large response; the message is that monetary policy prefers to act aggressively initially to prevent expectations from becoming unanchored. This way, the bank can avoid much larger interventions once expectations are massively unanchored.

This notion is reflected in the fact that the partial derivative of the interest rate policy with respect to the gain is non-monotonic. As panel (a) emphasizes, increases in the gain are associated with increases in the interest rate as long as the gain is small. Once the gain exceeds the value of 0.02, the interest rate response associated with increases in the gain becomes negative. This non-monotonicity is due to the fact that high gains lead to oscillatory forecast errors, which feed back into the observables, increasing inflation and output gap volatility. Therefore the central bank acts aggressively in the moment expectations are becoming unanchored to prevent unanchoring. Once expectations are already unanchored, fighting this becomes too costly in terms of inflation and output gap volatility, prompting the bank's less aggressive response.

This highlights another intertemporal tradeoff that complements the stabilization tradeoff discussed

³¹To be sure, I include the exogenous states in the regressor matrix to control for the effect of forecast errors on $\bar{\pi}$. Note also that whether $\bar{\pi}$ drifts up or down following an increase in the gain depends on the sign of the current forecast error. To control for this, I consider a sample where $\bar{\pi}$ is always positive.

³²Because of the non-monotonicity of the interest rate response to the gain, the optimal change in the interest rate for a same size unanchoring downward is a decrease of 0.4541 pp.

in Section 5.1: a volatility tradeoff. If expected mean inflation is anchored at the central bank’s target, zero, then even for shocks hitting the economy, the monetary authority need not intervene much because stable expectations lower the pass-through between shocks and observables. However, sufficiently large shocks can unanchor expectations, enabling them to act as a positive feedback loop between shocks, observables and expectations. In the long run, therefore, the central bank wishes to have expectations anchored.

The tradeoff stems from the fact that anchoring expectations itself comes at a volatility cost. Anchoring expectations requires an aggressive interest response because by this means, the central bank can introduce negative feedback to the system. A strong interest rate response initially increases forecast errors. Taken together with the fact that unanchored expectations involve having a large gain, and a large gain in turn implies highly oscillatory forecast errors, all this leads to large forecast errors oscillating with a high amplitude.³³ Thus expectations fluctuate vastly, and observables become volatile.³⁴

We can see from the policy function how optimal policy resolves the tradeoff: it reacts aggressively to increasing gains as long as the gain is small, but once it exceeds a threshold value, the interest rate response becomes moderate. This is the threshold at which the short-run volatility the central bank induces becomes too costly. To avoid having to pay so high a price, the central bank is extra aggressive in the short run to prevent massive unanchoring from ever materializing. Thus the optimal response to the volatility tradeoff is to temporarily increase volatility in order to reduce it in the long-run.

The presence of this volatility tradeoff also implies that optimal policy aggressiveness is yet again time-varying: the same shock involves a stronger interest rate response if expectations threaten to unanchor than otherwise. This result emerges clearly if one considers another way to investigate optimal policy in the model. I thus next compare the evolution of observables conditional on a particular history of exogenous disturbances across two specifications of monetary policy: one that follows the target criterion in (28) and one that follows a Taylor-rule with parameter values given in Table 1.³⁵

Fig. 4 depicts the evolution of inflation, the output gap and the interest rate conditional on a sequence of exogenous disturbances. Panels (a) and (b) show the outcome achieved by adhering to the Taylor rule and the target criterion (28) respectively. One clearly sees the features of optimal policy under anchoring compared to a standard Taylor-rule approach. Due to the low value of ψ_x here, the Taylor-rule-following central bank resolves the inflation-output gap tradeoff by allowing the output gap to sink far into negative territory and instead stabilizing inflation. Instead, optimal policy uses the interest rate tool much more aggressively to achieve a nearly identical inflation series, yet a much more

³³As periodically noted in the adaptive learning literature, constant gain learning models have a tendency to produce impulse responses that exhibit damped oscillations. Authors making explicit note of this phenomenon include Evans and Honkapohja (2001), Evans et al. (2013) and Anufriev and Hommes (2012). The reason is that under an adaptive learning framework, forecast errors following an impulse are oscillatory. In fact, the higher the learning gain, the higher the amplitude of forecast error oscillations. App. I presents a simple illustration for why this is the case.

³⁴App. J demonstrates the volatility cost of having unanchored expectations as well as of getting expectations anchored by plotting impulse responses of the model to a monetary policy shock. It also discusses the relationship between the model’s oscillatory impulse responses and Ball (1994)’s proposition of expansionary disinflations in NK models.

³⁵Given that in my calibration the central bank does not attach any weight to interest rate stabilization ($\lambda_i = 0$), this choice of Taylor-rule coefficients would not be optimal in the RE version of the model, since $\lambda_i = 0$ implies infinity as the optimal choice for both ψ_π and ψ_x . My choice of $\lambda_i = 0$ is motivated by keeping the interpretation as simple as possible.

Figure 4

stable output gap series. In particular early in the sample, the central bank is willing to raise and lower the interest rate massively in order to eliminate any potential of large-scale unanchoring. But even late in the sample, the interest rate can fluctuate wildly between $\pm 5\%$ in order to quench any potential unanchoring brought about by unforecastable disturbances. Thus one observes both features of optimal policy foreshadowed in the previous discussions: i) anchoring alleviates the intratemporal tradeoff between inflation and the output gap, ii) there is an intertemporal volatility tradeoff between the short-run cost and the long-run benefit of anchoring expectations, for which reason the central bank prefers to avoid expectations getting unanchored in the first place. A time-varying level of aggressiveness

is the result.

5.3 Optimal Taylor rule under anchoring

Monetary policy is often formulated using a Taylor rule. Proponents of such a characterization, like Taylor (1993) himself, emphasize the benefits of having a simple, time-invariant and easily verifiable rule. Also in the anchoring model, a policymaker may thus be interested in using a Taylor-type approximation to optimal policy in order to combine the benefits of having a simple, yet near-optimal rule.³⁶ Therefore I now consider the restricted set of Taylor-type policy rules and ask what value of the time-invariant Taylor-rule coefficient on inflation is optimal in the case of the anchoring model.³⁷

I compute the optimal Taylor rule coefficient on inflation numerically by minimizing the central bank's expected loss in a cross-section of $N = 100$ simulations of both the rational expectations and learning versions of the model. I continue to use the calibration of Table 1 and to parameterize the anchoring function using the estimated $\hat{\alpha}$ from Section 4.

Table 2 presents an overview of the optimal Taylor rule coefficient ψ_π for the rational expectations and anchoring models. The table also compares the baseline parameterization with several alternatives. One notices that if the central bank has no concern to stabilize the output gap ($\lambda_x = 0$) or the nominal interest rate ($\lambda_i = 0$), ψ_π^{RE} is infinity. This is because if the central bank suffers no loss upon output variation, then the fact that the divine coincidence is violated does not pose a problem. Similarly, if the monetary authority is willing to allow the nominal interest rate to fluctuate vastly in order to stabilize inflation, this also allows the central bank to be infinitely aggressive on inflation.

Table 2: Optimal coefficient on inflation, RE against anchoring for alternative parameters

| | $\psi_\pi^{*,RE}$ | $\psi_\pi^{*,anchoring}$ |
|-----------------|-------------------|--------------------------|
| Baseline | ∞ | 1.0228 |
| $\lambda_x = 1$ | 1.1284 | 1.0046 |
| $\lambda_i = 1$ | 1 | 1.019 |

The main observation however is that ψ_π is tendentially lower for the anchoring model than for the RE model. In particular, even absent a concern for interest rate stabilization ($\lambda_i = 0$), it is not optimal in the anchoring model to be infinitely aggressive on inflation. This is reinforced in Fig. 5 which plots the central bank's loss in the RE and learning models for the baseline specification, with various values of ψ_π . The message is clear: while for rational expectations, the loss is strictly decreasing in ψ_π , this is not the case for the anchoring model.

³⁶Recall from Woodford (2011) that even under rational expectations, a Taylor rule is not fully optimal. The reason is that the optimal commitment rational expectations version of the targeting rule (28) takes the form of (31) with an additional x_{t-1} term. This lagged term renders the solution history-dependent, which in turn allows the central bank to reap the benefits of commitment. Therefore, due to its purely forward-looking nature, a Taylor-type interest rate rule is only optimal in the restricted set of fully forward-looking policy rules. Since Result 2 tells us that in the anchoring model there is no distinction between commitment and discretion, this point may be less relevant here than for rational expectations.

³⁷To simplify the exposition, I continue entertaining a Taylor-coefficient on the output gap of zero.

This echoes the analytical results of Section 5.2: the anchoring mechanism introduces an intertemporal cost-benefit tradeoff for the central bank. On the one hand, as we will see shortly in Fig. 8, having unanchored expectations increases the volatility of the observables. This results in the central bank wishing to anchor expectations. As Fig. 9 makes clear, this requires raising ψ_π . But in an environment where agents know the Taylor rule, a higher coefficient on inflation will lead to initially higher volatility due to agents anticipating the endogenous responses of the nominal interest rate far in the future.

Figure 5: Central bank loss as a function of ψ_π

Sample length is $T = 400$ with a cross-section of $N = 100$.

Thus restricting the central bank's reaction function to a Taylor rule, I again encounter the intertemporal volatility tradeoff in addition to the tradeoffs discussed in Section 5.2. Unsurprisingly, it is desirable for the central bank to anchor expectations. It is also intuitive that being aggressive on inflation helps to anchor expectations. However, less intuitive is the fact that the optimal degree of aggressiveness on inflation is lower than under rational expectations. This has to do with the heightened volatility of the expectations process when ψ_π is high. A higher ψ_π increases the response of future nominal interest rate expectations, thus raising the feedback from expectations to current observables. Thus the intertemporal volatility tradeoff of Section 5.2 makes itself felt also here.

It has to be remarked that constraining the Taylor-rule coefficients to be time-invariant is also likely to drive the result. Since we know from Sections 5.1 and 5.2 that optimal policy is time-varying, it seems reasonable to expect that if the central bank were allowed to select time-varying Taylor-rule coefficients, it would choose low coefficients when expectations are anchored and high ones when expectations show signs of unanchoring.

5.4 Discussion

The analytical and numerical analysis of monetary policy in the anchoring model has led to the following conclusions. As seen in Result 2, optimal monetary policy is time-consistent and does not exhibit history-dependence. Therefore, optimal responses to shocks feature intertemporal stabilization tradeoffs that allow the central bank to postpone the intratemporal tradeoff between inflation and output gap stabilization to the future. Ironically, although the first-order conditions from the Ramsey problem

have the flavor of discretion due to the absence of lagged multipliers, the optimal response to shocks prescribed by the target criterion (28) qualitatively resembles commitment as it spreads out the effect of shocks over time.

The implementation of the target criterion calls for an interest rate policy function that is very responsive to the stance of expected mean inflation. As we saw in Section 5.2, an upward unanchoring of expectations brought about by a positive forecast error of 1 pp induces the central bank to raise the interest rate by 0.4547 pp. The simulation in Section 5.2 also shows that, accordingly, the optimal interest rate path is more volatile than a path generated by a standard Taylor rule, especially early in the sample. This comes from optimal policy responding aggressively to any sign of expectations threatening to become unanchored; a phenomenon that is especially likely early in the learning process.

At the same time, as seen in Section 5.3, restricting the central bank to follow a Taylor rule and choosing its response coefficients to minimize the central bank's loss function leads to lower Taylor-rule coefficients than under rational expectations. This reflects the intertemporal cost-benefit tradeoff the central bank faces as it seeks to anchor expectations but to avoid causing too much volatility by doing so.

Taken together, these results suggest that optimal policy aggressiveness should be time-varying: the central bank should condition its tolerance of inflation on the stance of anchoring. Since in the anchoring model volatility is increasing in aggressiveness, the central bank prefers to be less aggressive on inflation than under rational expectations in general. However, unanchored expectations also lead to higher volatility. To avoid volatility associated with unanchored expectations, then, the central bank needs to act more aggressively any time it sees signs of unanchoring. The policy function of Section 5.2 captures this notion as it expresses the interest rate choice as a function of the gain and expected mean inflation. If a central bank is reluctant to employ a policy function other than a Taylor rule, then my analysis underscores the conclusion of Lubik and Matthes (2016) that the optimal Taylor-rule coefficients should be time-varying. Alternatively, a term capturing the stance of anchoring - the gain or the private sector's expected mean inflation - could be included in the Taylor rule. This allows the central bank's actions to reflect the stance of anchoring in the way the optimal policy rule of Section 5.2 prescribes.

6 Conclusion

Central bankers frequently voice a concern to anchor expectations. Absent a behavioral theory of anchored expectations, it is difficult to understand how such a concern affects the conduct of monetary policy. In this paper, I have laid out a simple theory of anchoring expectation formation based on adaptive learning models with an endogenous gain. The estimation of the anchoring function and the analysis of the Ramsey policy through analytical and numerical methods yields a number of differences compared to the rational expectations version of the model.

The main message is that policy is time-varying because it responds to the unanchoring of expectations. The estimation shows that mistakes in the inflation forecast of about 1 pp begin to unanchor expectations. In this case, policy raises/lowers the interest rate by 0.4547 pp, depending on the sign of

the forecast error.

Optimal policy in the anchoring model is time-consistent, for which reason it can be expressed as a purely forward-looking target criterion for the policymaker to follow. The target criterion prescribes how the policymaker can exploit the learning mechanism to spread out the effect of shocks over time, adding an intertemporal channel to the tradeoff between inflation and the output gap. The sensitivity of the policy function to the stance of anchoring highlights, however, that there is no free lunch: the monetary authority needs to dampen volatility at the same time as guard against the possibility of unanchoring expectations. Thus optimal policy faces an intertemporal volatility tradeoff in which long-run stability can only be achieved at the cost of short-run volatility. [Carvalho et al. \(2019\)](#)’s estimate of the time series of the learning gain tells exactly this story on the example of the Volcker deflation: the rise and fall of volatility as the Fed sought to subdue unanchored expectations.

A number of interesting questions emerge from the analysis of monetary policy and the anchoring expectation formation. One may wonder whether the central bank can use tools other than its leading interest rate to anchor expectations. Especially concerns around a binding zero lower bound would motivate the use of alternative monetary policy tools. Thus the interaction between anchoring and central bank communication, in particular forward guidance, would be worthwhile to examine. An interesting avenue for future research, then, would be to make explicit the communication policy of the central bank to investigate whether anchoring expectation formation could help to resolve the forward guidance puzzle.

This, however, requires overcoming the implication of [Result 2](#) that adaptive expectations are not able to incorporate any information that is not embedded in the current state vector. One option is to model central bank communication similarly to news shocks in the sense of [Beaudry and Portier \(2006\)](#). In this case, the anchoring model is likely to deliver differing predictions regarding the effectiveness of Delphic versus Odyssean forward guidance ([Campbell et al. \(2012\)](#)) because sharing the central bank’s forecasts would not constitute a questioning of the interest rate reaction function, while committing to a future interest rate path would.

In general, extensions to the anchoring expectation formation proposed here would be of interest. The choice of the gain could be endogenized using approaches that allow the private sector to choose its forecasting behavior in an optimizing fashion, perhaps by selecting among competing forecasting models as in [Branch and Evans \(2011\)](#) or by choosing the size of the gain to minimize the estimated forecast error variance.

Lastly, a foray into the empirics of anchoring expectation formation is important to get a clearer idea of the expectation formation process of the public. In practice, it is likely that this process is heterogenous, not just across households and firms, but also within various demographic groups or sectors of the economy. If so, then monetary policy would need to collect and monitor a host of long-run expectations time series to manage the challenge of anchoring expectations.

A Compact model notation

The A-matrices are given by

$$A_a = \begin{pmatrix} g_{\pi a} \\ g_{xa} \\ \psi_\pi g_{\pi a} + \psi_x g_{xa} \end{pmatrix} \quad A_b = \begin{pmatrix} g_{\pi b} \\ g_{xb} \\ \psi_\pi g_{\pi b} + \psi_x g_{xb} \end{pmatrix} \quad A_s = \begin{pmatrix} g_{\pi s} \\ g_{xs} \\ \psi_\pi g_{\pi s} + \psi_x g_{xs} + \begin{bmatrix} 0 & 1 & 0 \end{bmatrix} \end{pmatrix} \quad (\text{A.1})$$

$$g_{\pi a} = \left(1 - \frac{\kappa\sigma\psi_\pi}{w}\right) \left[(1 - \alpha)\beta, \kappa\alpha\beta, 0\right] \quad (\text{A.2})$$

$$g_{xa} = \frac{-\sigma\psi_\pi}{w} \left[(1 - \alpha)\beta, \kappa\alpha\beta, 0\right] \quad (\text{A.3})$$

$$g_{\pi b} = \frac{\kappa}{w} \left[\sigma(1 - \beta\psi_\pi), (1 - \beta - \beta\sigma\psi_x), 0\right] \quad (\text{A.4})$$

$$g_{xb} = \frac{1}{w} \left[\sigma(1 - \beta\psi_\pi), (1 - \beta - \beta\sigma\psi_x), 0\right] \quad (\text{A.5})$$

$$g_{\pi s} = \left(1 - \frac{\kappa\sigma\psi_\pi}{w}\right) \begin{bmatrix} 0 & 0 & 1 \end{bmatrix} (I_3 - \alpha\beta h)^{-1} - \frac{\kappa\sigma}{w} \begin{bmatrix} -1 & 1 & 0 \end{bmatrix} (I_3 - \beta h)^{-1} \quad (\text{A.6})$$

$$g_{xs} = \frac{-\sigma\psi_\pi}{w} \begin{bmatrix} 0 & 0 & 1 \end{bmatrix} (I_3 - \alpha\beta h)^{-1} - \frac{\sigma}{w} \begin{bmatrix} -1 & 1 & 0 \end{bmatrix} (I_3 - \beta h)^{-1} \quad (\text{A.7})$$

$$w = 1 + \sigma\psi_x + \kappa\sigma\psi_\pi \quad (\text{A.8})$$

The matrices of the state transition equation (14) are

$$h \equiv \begin{pmatrix} \rho_r & 0 & 0 \\ 0 & \rho_i & 0 \\ 0 & 0 & \rho_u \end{pmatrix} \quad \epsilon_t \equiv \begin{pmatrix} \varepsilon_t^r \\ \varepsilon_t^i \\ \varepsilon_t^u \end{pmatrix} \quad \text{and} \quad \eta \equiv \begin{pmatrix} \sigma_r & 0 & 0 \\ 0 & \sigma_i & 0 \\ 0 & 0 & \sigma_u \end{pmatrix} \quad (\text{A.9})$$

Note that this is the formulation for the case where a Taylor rule is in effect and is known by the private sector. It is straightforward to remove any of these two assumptions.

B The observation matrix for learning

Instead of the matrix g in the rational expectations observation equation

$$z_t = g s_t \quad (\text{B.1})$$

agents in the anchoring model use the estimated matrix g^l

$$g_{t-1}^l = \begin{bmatrix} F_{t-1} & G_{t-1} \end{bmatrix} \quad (\text{B.2})$$

with

$$F_{t-1} = \left(A_a \frac{1}{1 - \alpha\beta} + A_b \frac{1}{1 - \beta} \right) a_{t-1} \quad (\text{B.3})$$

$$G_{t-1} = A_a b_{t-1} \left(I_3 - \alpha\beta h \right)^{-1} + A_b b_{t-1} \left(I_3 - \beta h \right)^{-1} + A_s \quad (\text{B.4})$$

C Alternative specifications for the anchoring function

The general law of motion for the gain in the main text is given by Equation (21), reproduced here for convenience:

$$k_t = \mathbf{g}(k_{t-1}, fe_{t|t-1}) \quad (\text{C.1})$$

The baseline specification of the anchoring function \mathbf{g} (Equation (24) in the main text) is

$$\mathbf{g} = \alpha b(fe_{t|t-1}) \quad (\text{C.2})$$

where $b(fe_{t|t-1})$ is the second order spline basis and $\hat{\alpha}$ are the coefficients estimated in Section 4.

To my knowledge, there are only two other papers that consider an endogenous gain as a model for anchored expectations. The first one, more related to this paper, is [Carvalho et al. \(2019\)](#). In their model, the anchoring function is a discrete choice function as follows. Let θ_t be a criterion to be defined. Then, for a threshold value $\tilde{\theta}$, the gain evolves according to

$$k_t = \begin{cases} (k_{t-1} + 1)^{-1} & \text{if } \theta_t < \tilde{\theta} \\ \bar{g} & \text{otherwise.} \end{cases} \quad (\text{C.3})$$

In other words, agents choose a decreasing gain when the criterion θ_t is lower than the threshold $\tilde{\theta}$; otherwise they choose a constant gain. The criterion employed by [Carvalho et al. \(2019\)](#) is computed as the absolute difference between subjective and model-consistent expectations, scaled by the variance of shocks:

$$\theta_t = \max |\Sigma^{-1}(\phi_{t-1} - [F_{t-1} \ G_{t-1}])| \quad (\text{C.4})$$

where Σ is the VC matrix of shocks, ϕ_{t-1} is the estimated matrix and $[F, G]$ is the ALM (see App. B).

As a robustness check, [Carvalho et al. \(2019\)](#) also compute an alternative criterion.³⁸ Let ω_t denote agents' time t estimate of the forecast error variance and θ_t be a statistic evaluated by agents in every period as

$$\omega_t = \omega_{t-1} + \tilde{\kappa} k_{t-1} (fe'_{t|t-1} fe'_{t|t-1} - \omega_{t-1}) \quad (\text{C.5})$$

$$\theta_t = \theta_{t-1} + \tilde{\kappa} k_{t-1} (fe'_{t|t-1} \omega_t^{-1} fe_{t|t-1} - \theta_{t-1}) \quad (\text{C.6})$$

where $\tilde{\kappa}$ is a parameter that allows agents to scale the gain compared to the previous estimation and

³⁸Note that for both criteria, I present the matrix generalizations of the scalar versions considered by [Carvalho et al. \(2019\)](#).

$fe_{t|t-1}$ is the most recent forecast error, realized at time t . Indeed, this is a multivariate time series version of the squared CUSUM test.³⁹

It is interesting to compare the two discrete anchoring functions with my smooth specification. On the one hand, the [Carvalho et al. \(2019\)](#)’s preferred specification requires the private sector to evaluate model-consistent expectations, which runs counter to the maintained informational assumptions. It is more consistent with the present model, then, to assume that firms and households employ a statistical test of structural change, as is the case with the CUSUM-based and smooth functions. These are therefore more appealing on conceptual grounds.

On the other hand, simulation of the model using the different anchoring specifications reveals that [Carvalho et al. \(2019\)](#)’s preferred functional form leads to the opposite comparative statics of anchoring with respect to monetary policy aggressiveness as the smooth or the CUSUM-based specifications. In particular, while policy that is more aggressive on inflation (a higher ψ_π in the Taylor rule) leads to more anchoring in a model with the smooth or the CUSUM-inspired criterion. If one uses [Carvalho et al. \(2019\)](#)’s criterion, the same comparative static involves *less* anchoring. This comes from the fact that [Carvalho et al. \(2019\)](#)’s criterion endows the public sector with capabilities to disentangle volatility due to the learning mechanism from that owing to exogenous disturbances. Thus agents in the [Carvalho et al. \(2019\)](#) model are able to make more advanced inferences about the performance of their forecasting rule and understand that a higher ψ_π causes more learning-induced volatility. This is however not possible for agents who process data in real time without knowledge of the model. Therefore my smooth and the discrete CUSUM-inspired specifications are preferable both on conceptual and quantitative grounds.

Whether one relies on the discrete CUSUM or my smooth anchoring function, then, is a question of application. The analytical analysis of this paper requires derivatives of the anchoring function to exist. In such a case, the smooth specification is necessary. The discrete choice specification is easier to work with when computing moments conditional whether expectations are anchored or not because it only requires keeping track of two discrete cases.

The second paper with an anchoring function is [Gobbi et al. \(2019\)](#). In their model, which is a three-equation New Keynesian model, firms and households entertain the possibility that the model may switch from a “normal” regime to a liquidity trap regime that the authors name the “new normal.” Expectations are a probability-weighted average of the regime-specific expectations. The concept of unanchoring in the model is when p , the probability of the liquidity trap regime, rises significantly. The function governing the evolution of p , which [Gobbi et al. \(2019\)](#) refer to as the deanchoring function (DA), is the analogy to my anchoring function. The authors use the following logistic specification for the DA function:

$$p = h(y_{t-1}) = A + \frac{BCe^{-Dy_{t-1}}}{(Ce^{-Dy_{t-1}} + 1)^2} \quad (\text{C.7})$$

where y_{t-1} denotes the output gap and A, B, C and D are parameters.

³⁹See [Brown et al. \(1975\)](#) and [Lütkepohl \(2013\)](#) for details.

D Estimation procedure

The estimation of Section 4 is a simulated method of moments (SMM) exercise. As elaborated in the main text, I target the autocovariances of CPI inflation, the output gap, the federal funds rate and the 12-months ahead inflation forecasts coming from the Survey of Professional Forecasters. For the autocovariances, I consider lags $0, \dots, 4$. The target moment vector, Ω , is the vectorized autocovariance matrices for the lags considered, 80×1 .

For each proposed coefficient vector α , the estimation procedure consists of simulating the model conditional on α , the calibrated parameters θ and N different sequences of disturbances, computing model-implied moments for each simulation, and lastly choosing α such that the squared distance between the data- and model-implied mean moments is minimized. Thus

$$\hat{\alpha} = \left(\Omega^{data} - \frac{1}{N} \sum_{n=1}^N \Omega^{model}(\alpha, \theta, \{e_t^n\}_{t=1}^T) \right)' W^{-1} \left(\Omega^{data} - \frac{1}{N} \sum_{n=1}^N \Omega^{model}(\alpha, \theta, \{e_t^n\}_{t=1}^T) \right) \quad (D.1)$$

where the observed data is of length $T = 155$ quarters. Here $\{e_t^n\}_{t=1}^T$ is a sequence of disturbances of the same length as the data; note that I use a cross-section of N such sequences and take average moments across the cross-section to wash out the effects of particular disturbances. Experimentation with the number N led me to choose $N = 1000$, as estimates no longer change upon selecting larger N .

Before computing moments, I filter both the observed and model-generated data using the [Baxter and King \(1999\)](#) filter, with thresholds at 6 and 32 quarters and truncation at 12 lags, the recommended values of the authors. As the weighting matrix of the quadratic form in the moments, I use the inverse of the estimated variances of the target moments, W^{-1} , computed from 10000 bootstrapped samples.

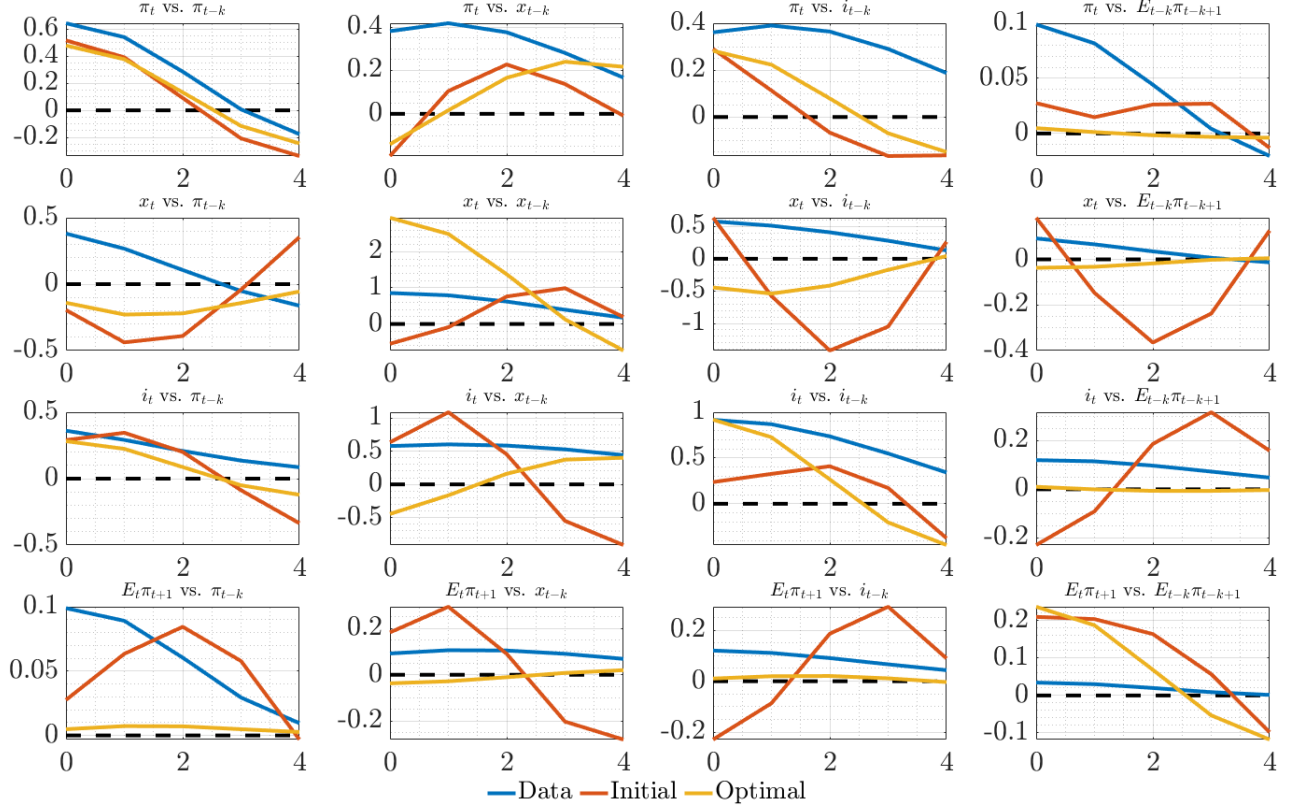

To improve identification, I also impose restrictions on the estimates. First, I require that the α -coefficients be convex, that is, that larger forecast errors in absolute value be associated with higher gains. Second, since forecast errors close to zero render the size of the gain irrelevant (cf. the learning equation (19)), I impose that the coefficient associated with a zero forecast error should be zero. Both restrictions are implemented with weights penalizing the loss function, and the weights are selected by experimentation.

Both additional assumptions reflect properties that it is reasonable to expect the anchoring function to have. The convexity assumption captures the very notion that larger forecast errors in absolute value suggest bigger changes to the forecasting procedure are necessary. This is thus a very natural requirement. As for the zero gain for zero forecast error assumption, the idea here is to supply the estimation with information where it is lacking. Since the updating of learning coefficients corresponds to gain times forecast error, as Equation (19) recalls, a zero forecast error supplies no information for the value of the gain. To impose a zero value here also seems natural, given that since forecast errors switch sign at zero, one would expect the zero forecast error point to be an inflection point in the anchoring function. By the same token, [Gobbi et al. \(2019\)](#) also impose a related restriction when they require that their deanchoring function should yield a zero value at the zero input. Lastly, the objective function does not deteriorate upon imposing either assumption, suggesting that they are not at odds

with the data.

Fig. 6 presents the autocovariances of the observed variables for the estimated coefficients.

Figure 6: Autocovariogram

Estimates for $N = 1000$, imposing convexity with weight 100K

E The policy problem in the simplified baseline model

Denote by $\mathbf{g}_{i,t} \in (0, 1)$, $i = \pi, \bar{\pi}$, the potentially time-varying derivatives of the anchoring function \mathbf{g} . In this simplified setting, $\bar{\pi}_t = e_1 a_t$, the estimated constant for the inflation process. e_i is a selector vector, selecting row i of the subsequent matrix. I also use the notation $b_i \equiv e_i b$. The planner chooses $\{\pi_t, x_t, f_{a,t}, f_{b,t}, \bar{\pi}_t, k_t\}_{t=t_0}^{\infty}$ to minimize

$$\mathcal{L} = \mathbb{E}_{t_0} \sum_{t=t_0}^{\infty} \beta^{t-t_0} \left\{ (\pi_t^2 + \lambda_x x_t^2) \right. \quad (\text{E.1})$$

$$\left. + \varphi_{1,t} \left(\pi_t - \kappa x_t - (1 - \alpha) \beta f_{a,t} - \kappa \alpha \beta b_2 (I_3 - \alpha \beta h)^{-1} s_t - e_3 (I_3 - \alpha \beta h)^{-1} s_t \right) \right. \quad (\text{E.2})$$

$$\left. + \varphi_{2,t} \left(x_t + \sigma i_t - \sigma f_{b,t} - (1 - \beta) b_2 (I_3 - \beta h)^{-1} s_t + \sigma \beta b_3 (I_3 - \beta h)^{-1} s_t - \sigma e_1 (I_3 - \beta h)^{-1} s_t \right) \right\} \quad (\text{E.3})$$

$$+ \varphi_{3,t} \left(f_{a,t} - \frac{1}{1 - \alpha \beta} \bar{\pi}_{t-1} - b_1 (I_3 - \alpha \beta h)^{-1} s_t \right) \quad (\text{E.4})$$

$$+ \varphi_{4,t} \left(f_{b,t} - \frac{1}{1 - \beta} \bar{\pi}_{t-1} - b_1 (I_3 - \beta h)^{-1} s_t \right) \quad (\text{E.5})$$

$$+ \varphi_{5,t} \left(\bar{\pi}_t - \bar{\pi}_{t-1} - k_t (\pi_t - (\bar{\pi}_{t-1} + b_1 s_{t-1})) \right) \quad (\text{E.6})$$

$$+ \varphi_{6,t} \left(k_t - \mathbf{g}(\pi_t - \bar{\pi}_{t-1} - b_1 s_{t-1}) \right) \left. \right\} \quad (\text{E.7})$$

where ρ_i are Lagrange-multipliers on the constraints. After a little bit of simplifying, the first-order conditions boil down to the following three equations:

$$2\pi_t + 2 \frac{\lambda_x}{\kappa} x_t - \varphi_{5,t} k_t - \varphi_{6,t} \mathbf{g}_{\pi,t} = 0 \quad (\text{E.8})$$

$$- \frac{2(1 - \alpha) \beta \lambda_x}{1 - \alpha \beta} \frac{x_t}{\kappa} + \varphi_{5,t} - (1 - k_t) \varphi_{5,t+1} + \mathbf{g}_{\pi,t} \varphi_{6,t+1} = 0 \quad (\text{E.9})$$

$$\varphi_{6,t} = (\pi_t - \bar{\pi}_{t-1} - b_1 s_{t-1}) \varphi_{5,t} \quad (\text{E.10})$$

Note that Equation (E.8) is the analogue of Gaspar et al. (2010)'s Equation (22) (or, equivalently, of Molnár and Santoro (2014)'s (16)), except that there is an additional multiplier, φ_6 . This multiplier reflects the fact that in addition to the constraint coming from the expectation process itself, with shadow value φ_5 , learning involves the gain equation as a constraint as well. One can also clearly read off Result 2: when the learning process has converged such that neither expectations nor the gain process are constraints ($\varphi_5 = \varphi_6 = 0$), the discretionary inflation-output gap tradeoff familiar from Clarida et al. (1999) obtains. Combining the above three equations and solving for $\varphi_{5,t}$, using the notation that $\prod_{j=1}^0 \equiv 1$, one obtains the target criterion (28).

The system of first-order conditions (32)-(33) and model equations for this simplified system also reveal how the endogenous gain introduces nonlinearity to the equation system. In particular, notice how in equations (32)-(33), the gain k_t shows up multiplicatively with the Lagrange multiplier, $\varphi_{2,t}$. In fact, the origin of the problem is the recursive least squares learning equation for the learning coefficient f_t

$$f_t = f_{t-1} + k_t (\pi_t - f_{t-1}) \quad (\text{E.11})$$

where the first interaction terms between the gain and other endogenous variables show up. This results in an equation system of nonlinear difference equations that does not admit an analytical solution.

Considering equation (E.11) is instructive to see how it is indeed the endogeneity of the gain that causes these troubles. Were we to specify a constant gain setup, k_t would merely equal the constant \bar{g} and the anchoring function \mathbf{g} would trivially reduce to zero as well. In such a case, all interaction terms would reduce to multiplication between endogenous variables and parameters; linearity would be restored and a solution for the optimal time paths of endogenous variables would be obtainable. Similarly, a decreasing gain specification would also be manageable since for all t , the gain would simply be given by t^{-1} , and the anchoring function would also be deterministic and exogenous.

F A target criterion for an anchoring mechanism specified in terms of gain changes

Consider the general anchoring mechanism of Equation (21):

$$k_t = \rho_k k_{t-1} + \mathbf{g}(fe_{t|t-1}) \quad (\text{F.1})$$

With this assumption, the FOCs of the Ramsey problem are

$$2\pi_t + 2\frac{\lambda_x}{\kappa}x_t - k_t\varphi_{5,t} - \mathbf{g}_{\pi,t}\varphi_{6,t} = 0 \quad (\text{F.2})$$

$$cx_{t+1} + \varphi_{5,t} - (1 - k_t)\varphi_{5,t+1} + \mathbf{g}_{\pi,t}\varphi_{6,t+1} = 0 \quad (\text{F.3})$$

$$\varphi_{6,t} + \varphi_{6,t+1} = fe_{t|t-1}\varphi_{5,t} \quad (\text{F.4})$$

where the red multiplier is the new element vis-à-vis the case where the anchoring function is specified in levels ($k_t = \mathbf{g}(fe_{t|t-1})$), and I'm using the shorthand notation

$$c = -\frac{2(1-\alpha)\beta}{1-\alpha\beta} \frac{\lambda_x}{\kappa} \quad (\text{F.5})$$

$$fe_{t|t-1} = \pi_t - \bar{\pi}_{t-1} - b_1 s_{t-1} \quad (\text{F.6})$$

(E.8) says that in anchoring, the discretion tradeoff is complemented with tradeoffs coming from learning ($\varphi_{5,t}$), which are more binding when expectations are unanchored (k_t^{-1} high). Moreover, the change in the anchoring of expectations imposes an additional constraint ($\varphi_{6,t}$), which is more strongly binding if the gain responds strongly to inflation ($\mathbf{g}_{\pi,t}$ is high in absolute value). One can simplify this three-equation-system to:

$$\varphi_{6,t} = -cfe_{t|t-1}x_{t+1} + \left(1 + \frac{fe_{t|t-1}}{fe_{t+1|t}}(1 - k_{t+1}^{-1}) - fe_{t|t-1}\mathbf{g}_{\pi,t}\right)\varphi_{6,t+1} - \frac{fe_{t|t-1}}{fe_{t+1|t}}(1 - k_{t+1}^{-1})\varphi_{6,t+2} \quad (\text{F.7})$$

$$0 = 2\pi_t + 2\frac{\lambda_x}{\kappa}x_t - \left(\frac{k_t}{fe_{t|t-1}} + \mathbf{g}_{\pi,t}\right)\varphi_{6,t} + \frac{k_t}{fe_{t|t-1}}\varphi_{6,t+1} \quad (\text{F.8})$$

Thus a central bank that follows the target criterion has to compute $\varphi_{6,t}$ as the solution to (F.8), and then evaluate (F.7) as a target criterion. The solution to (F.8) is given by:

$$\varphi_{6,t} = -2 \mathbb{E}_t \sum_{i=0}^{\infty} \left(\pi_{t+i} + \frac{\lambda_x}{\kappa} x_{t+i} \right) \prod_{j=0}^{i-1} \frac{\frac{k_{t+j}}{f e_{t+j|t}}}{\frac{k_{t+j}}{f e_{t+j|t}} + \mathbf{g}_{\pi,t+j}} \quad (\text{F.9})$$

The interpretation of (F.9) is that the anchoring constraint is not binding ($\varphi_{6,t} = 0$) if the central bank always hits the target ($\pi_{t+i} + \frac{\lambda_x}{\kappa} x_{t+i} = 0, \forall i$); or expectations are always anchored ($k_{t+j} = 0, \forall j$).

G Parameterized expectations algorithm (PEA)

The objective of the parameterized expectations algorithm is to solve for the sequence of interest rates that solves the model equations including the target criterion, representing the first-order condition of the Ramsey problem. For convenience, I list the model equations:

$$x_t = -\sigma i_t + \begin{bmatrix} \sigma & 1 - \beta & -\sigma\beta \end{bmatrix} f_{b,t} + \sigma \begin{bmatrix} 1 & 0 & 0 \end{bmatrix} (I_3 - \beta h)^{-1} s_t \quad (\text{G.1})$$

$$\pi_t = \kappa x_t + \begin{bmatrix} (1 - \alpha)\beta & \kappa\alpha\beta & 0 \end{bmatrix} f_{a,t} + \begin{bmatrix} 0 & 0 & 1 \end{bmatrix} (I_3 - \alpha\beta h)^{-1} s_t \quad (\text{G.2})$$

$$f_{a,t} = \frac{1}{1 - \alpha\beta} \bar{\pi}_{t-1} + b(I_3 - \alpha\beta h)^{-1} s_t \quad (\text{G.3})$$

$$f_{b,t} = \frac{1}{1 - \beta} \bar{\pi}_{t-1} + b(I_3 - \beta h)^{-1} s_t \quad (\text{G.4})$$

$$f e_{t|t-1} = \pi_t - (\bar{\pi}_{t-1} + b_1 s_{t-1}) \quad (\text{G.5})$$

$$k_t^{-1} = \gamma_k f e_{t|t-1}^2 \quad (\text{G.6})$$

$$\bar{\pi}_t = \bar{\pi}_{t-1} + k_t f e_{t|t-1} \quad (\text{G.7})$$

$$\pi_t = -\frac{\lambda_x}{\kappa} \left\{ x_t - \frac{(1 - \alpha)\beta}{1 - \alpha\beta} \left(k_t + f e_{t|t-1} \mathbf{g}_{\pi,t} \right) \left(\mathbb{E}_t \sum_{i=1}^{\infty} x_{t+i} \prod_{j=0}^{i-1} (1 - k_{t+1+j}^{-1} - (f e_{t+1+j|t+j}) \mathbf{g}_{\bar{\pi},t+j}) \right) \right\} \quad (\text{G.8})$$

Denote the expectation on the right hand side of (G.8) as E_t . The idea of the PEA is to approximate this expectation and to solve model equations given the approximation \hat{E}_t . The algorithm is as follows:⁴⁰

Objective: Obtain the sequence $\{i_t\}_{t=1}^T$ that solves Equations (G.1) - (G.8) for a history of exogenous shocks $\{s_t\}_{t=1}^T$ of length T .

1. Conjecture an initial expectation $\hat{E}_t = \beta^0 s(X_t)$.

The expectation is approximated as a projection on a basis, $s(X_t)$, where β^0 are initial projection coefficients, and $X_t = (k_t, \bar{\pi}_{t-1}, r_t^n, u_t)$ is the state vector. I use a monomial basis consisting of the first, second and third powers of X_t .

⁴⁰For a thorough treatment of the PEA, the interested reader is referred to [Christiano and Fisher \(2000\)](#).

2. Solve model equations given conjectured \hat{E}_t for a given sequence of shocks $\{s_t\}_{t=1}^T$.
 Compute residuals to the model equations (G.1) - (G.8) given $\{s_t\}_{t=1}^T$ and $\{\hat{E}_t\}_{t=1}^T$. Obtain a sequence $\{i_t\}_{t=1}^T$ that sets the residuals to zero. The output of this step is $\{v_t\}_{t=1}^T$, the simulated history of endogenous variables (Christiano and Fisher (2000) refer to this as “synthetic time series”).
3. Compute realized analogues of $\{E_t\}_{t=1}^T$ given $\{v_t\}_{t=1}^T$.
4. Update β regressing the synthetic E_t on $s(X_t)$.
 The coefficient update is $\beta^{i+1} = (s(X_t)'s(X_t))^{-1}s(X_t)'E_t$. Then iterate until convergence by evaluating at every step $\|\beta^i - \beta^{i+1}\|$.

H Parametric value function iteration

This is an alternative approach I implement as a robustness check to the PEA. The objective is thus the same: to obtain the interest rate sequence that solves the model equations. The general value iteration approach is fairly standard, for which reason I refer to the Judd (1998) textbook for details. Specific to my application is that the state vector is six-dimensional, $X_t = (k_t, \bar{\pi}_{t-1}, r_t^n, u_t, r_{t-1}^n, u_{t-1})$, and I approximate the value function using a cubic spline. Thus the output of the algorithm is a cubic spline approximation of the value function and a policy function for each node on the grid of states. Next, I interpolate the policy function using a cubic spline. As a last step I pass the state vector from the PEA simulation, obtaining an interest rate sequence conditional on the history of states. Fig. ?? shows the resulting interest rate sequence, obtained through the two approaches, conditional on two different simulated sequences for the states.

I Oscillatory dynamics in adaptive learning models

Here I present an illustration for why adaptive learning models produce oscillatory impulse responses if the gain is high enough. Consider a stylized adaptive learning model in two equations:

$$\pi_t = \beta f_t + u_t \tag{I.1}$$

$$f_t = f_{t-1} + k^{-1}(\pi_t - f_{t-1}) \tag{I.2}$$

The reader can recognize in (I.1) a simplified Phillips curve in which I am abstracting from output gaps to keep the presentation as clear as possible. Like in the simple model of Section 5.1 in the main text, f_t represents the one-period inflation expectation $\hat{\mathbb{E}}_t \pi_{t+1}$. (I.2), then, represents the simplest possible recursive updating of the expectations f_t . My notation of the gain as k^{-1} indicates a constant gain specification, but the intuition remains unchanged for decreasing (or endogenous) gains.

Combining the two equations allows one to solve for the time series of expectations

$$f_t = \frac{1 - k^{-1}}{1 - k^{-1}\beta} f_{t-1} + \frac{k^{-1}}{1 - k^{-1}\beta} u_t \tag{I.3}$$

Figure 7: Policy function for two particular histories of states, X^{PEA}

which, for β close but smaller than 1, is a near-unit-root process. (In fact, if the gain were to go to zero, this would be a unit root process.) Defining the forecast error as $fe_{t|t-1} \equiv \pi_t - f_{t-1}$, one obtains

$$fe_{t|t-1} = -\frac{1-\beta}{1-k^{-1}\beta}f_{t-1} + \frac{1}{1-k^{-1}\beta}u_t \quad (\text{I.4})$$

Equation (I.4) shows that in this simple model, the forecast error loads on a near-unit-root process with a coefficient that is negative and less than one in absolute value. Damped oscillations are the result.

Note that even if the gain would converge to zero, the coefficient on f_{t-1} would be negative and less than one in absolute value. Thus even for decreasing gain learning, one obtains oscillations, but the lower the gain, the more damped the oscillations become. This corroborates my findings in the impulse responses of Fig. 8. But importantly, the opposite extreme, when $k^{-1} \rightarrow 1$, results in a coefficient of exactly -1 , giving perpetual oscillations. This clearly illustrates how the oscillatory behavior of impulse responses comes from the oscillations in the forecast error that obtain when the gain is sufficiently large.

J Impulse responses in the anchoring model

Fig. 8 portrays the impulse responses of the model after a contractionary monetary policy shock. The red dashed lines show the responses of the observables in the rational expectations version of the model. The blue lines show the responses in the learning model, on panel (a) conditional on expectations being anchored when the shock hits, on panel (b) being unanchored upon the arrival of the shock.

Figure 8: Impulse responses after a contractionary monetary policy shock

(a) RE against anchoring, expectations anchored

(b) RE against anchoring, expectations unanchored

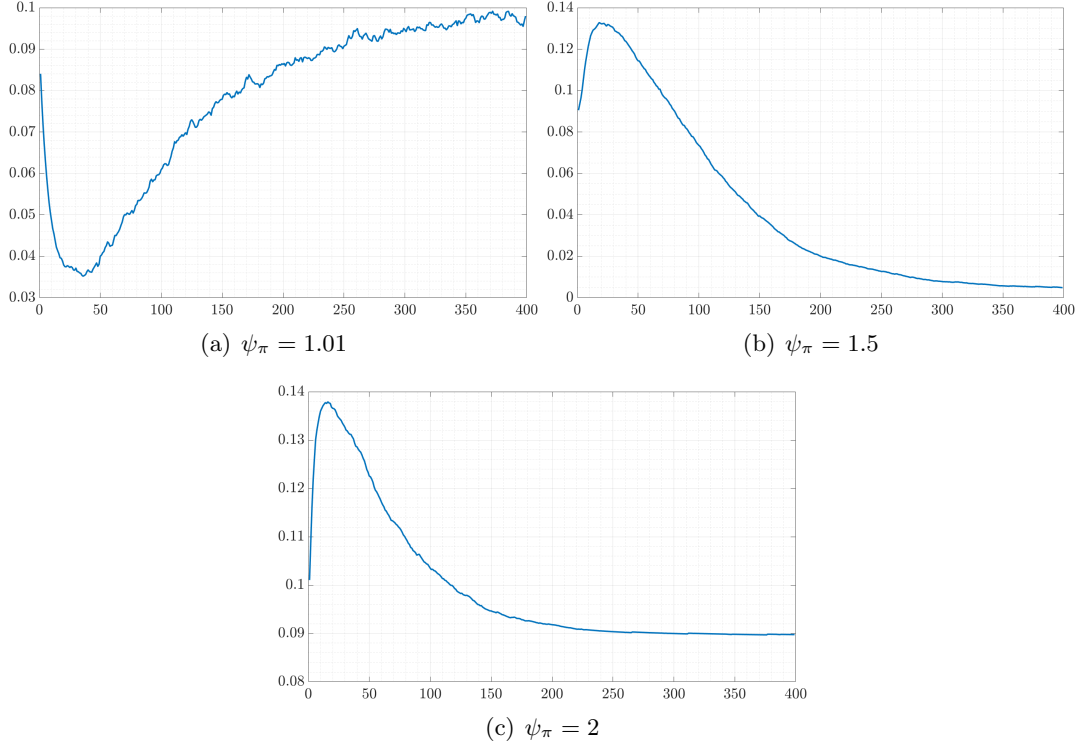

Shock imposed at $t = 25$ of a sample length of $T = 400$ (with 5 initial burn-in periods), cross-sectional average with a cross-section size of $N = 1000$. For the anchoring model, the remark refers to whether expectations are anchored at the time the shock hits.

Not only do the impulse responses show the usual behavior of learning models - dampened responses and increased persistence. More importantly, responses differ strongly depending on whether expectations are anchored or not when the shock hits. In particular, if expectations are anchored, responses are closer to rational expectations than when expectations are unanchored. Moreover, when expectations are unanchored, the endogenous responses of the observables become much more volatile, indeed, oscillatory⁴¹. This makes intuitive sense: expectations being unanchored reflects the fact that firms and households are confronted with an environment that does not line up with their currently held

⁴¹See App. I for an explanation of how forecast errors are responsible for the oscillatory dynamics.

perceived law of motion. They thus believe that a structural change has occurred and are therefore revising their expectations. Expectations are therefore fluctuating strongly, and as they feed back to the observables, the latter inherit their volatility.

Figure 9: Cross-sectional average gains for various values of ψ_π

Sample length is $T = 400$ (with 5 initial burn-in periods), cross-section size is $N = 1000$.

Fig. 9 shows the cross-sectional average of gains that result when ψ_π takes on different values. Clearly, a higher ψ_π results in lower and decreasing gains.⁴² Thus a central bank aiming to anchor expectations needs to employ a high ψ_π .

Fig. 10 which depicts the same impulse responses to a contractionary monetary policy shock as Fig. 8, focusing however only on responses conditional on expectations being unanchored upon the shock. It shows these responses for three different values of ψ_π .

As the figure shows, a high ψ_π leads to more volatility than a low one does. The intuition is a little subtle. Since expectations are unanchored, they are also volatile because the gain is high. This implies that expected inflation far ahead in the future fluctuates strongly. Since agents know the Taylor rule, this also means that they expect the nominal interest rate far in the future to respond. The more aggressive the central bank, the stronger an interest rate response will the agents expect. This however feeds back into current output gaps and thus inflation. Higher overall volatility is the result.

Unexpectedly, the model dynamics here echo the predictions of Ball (1994). But the underlying channels are quite different. Ball (1994) observes that, contrary to conventional wisdom, rational

⁴²As I remark in App. C, if one uses the anchoring function of Carvalho et al. (2019), this conclusion is overturned.

Figure 10: Impulse responses for unanchored expectations for various values of ψ_π

(a) $\psi_\pi = 1.01$

(b) $\psi_\pi = 1.5$

(c) $\psi_\pi = 2$

Shock imposed at $t = 25$ of a sample length of $T = 400$ (with 5 initial burn-in periods), cross-sectional average with a cross-section size of $N = 1000$.

expectations New Keynesian models imply expansionary disinflations. To reconcile this model feature with data pointing to the costliness of disinflations, he concludes that central bank announcements must suffer from credibility issues.

Note that in the present context, when expectations are anchored (Panel (a) of Fig. 8), impulse responses do not exhibit this feature. However, when expectations are unanchored (Panel (b) of Fig. 8), impulse responses look exactly as Ball (1994) predicts: we obtain an expansionary disinflation.

The reason this is happening is the above-mentioned fact that when agents know the Taylor rule, long-horizon expectations of the interest rate move in tandem with the same expectations of inflation in the far future. A current disinflation lowers long-horizon inflation expectations, leading the public to expect low interest rates far out in the future. Through the NKIS-curve (Equation 9), this stimulates current output.⁴³ But the absence of the “Ball-effect” from the anchored expectations impulse responses indicates that the channel is only operational when expectations are moving sufficiently. Thus I arrive at a different conclusion than Ball (1994); instead of credibility issues, it is anchored expectations that are responsible for the absence of expansionary disinflations of the type seen on Fig 8, panel (b).

⁴³The extension in which the public has to learn the Taylor rule is interesting in this regard. As expected, the Ball-type disinflationary boom does not initially show up in impulses responses obtained in that extension. However, as the agents are learning the Taylor rule, the expansionary disinflation slowly reemerges in the impulse responses.
